Mercury is often found native, in globules disseminated through its ores; it occurs also combined with silver and with gold, in the form of amalgams; also as iodide and chloride, and very rarely as selenide; but the most abundant ore is the sulphide, or cinnabar, from which nearly all the mercury of commerce is obtained. Its most important mines are those of Idria in Illyria, and of Almaden in Spain. At Almaden it is found in veins, often nearly fifty feet thick, traversing micaceous schists of the older transition period; in Illyria it is disseminated in beds of grit, bituminous schist, or compact limestone of more recent date. It occurs also in the Bavarian Palatinate, at Horowitz in Bohemia, at Schemnitz in Hungary, and a few other localities in Europe; on the Ural and Altai mountains; in China abundantly, and in Japan; at San Onofre, in Mexico; abundantly at Huanca Velica, in Southern Peru; in the province of Coquimbo, Chile; and forms extensive mines at New Almaden in California.

Preparation.—By distilling mercurial ores with lime, smithy-scales, or simply in contact with the air, so as to remove the sulphur by formation of sulphide of calcium, sulphide of iron, or sulphurous anhydride; partly also to remove chlorine. In the Bavarian Palatinate, a mixture of ore and lime is heated to redness in long cast-iron bottles, placed in nearly horizontal rows, one above the other in a long furnace, and provided with receivers. At Horowitz, in Bohemia, a mixture of ore and smithy-scales is placed in iron dishes, which are attached one above the other by the centres of their bases to a vertical iron axis, and covered over with an iron receiver, closed at top, and dipping into water at bottom. The upper part of the receiver is surrounded by the furnace, and imparts its heat to the dishes, from which the mercury rises in vapour, and collects in the water contained in the trough. This process is called *Destillatio per descensum*. At Idria, in Illyria, the quicksilver-ore, coarsely broken up, is laid upon a perforated stone arch, in a turret-shaped furnace, and after the apertures by which it is introduced have been stopped, heated to redness by flames made to play against the under surface of the arch. The sulphur is burnt by the air, which is admitted through channels constructed for the purpose; and the mixture of mercurial vapour, sulphurous acid, and smoke from the furnace, is made to pass through a horizontal channel constructed in the upper part of the furnace, then up and down through seven condensing chambers, and finally through a turret-shaped forge into the air. In the course of this long transit, the mercury condenses in the chambers, the floor of which, being inclined to one side, enables it to run out; it is then collected, and strained through coarse cloth. A similar process is followed at Almaden, in Spain, excepting that the vapours, instead of passing through condensing chambers, are made to traverse a series of tubes made up of cylinders, called *Aludels* (i. 149), open at both ends, and fitting one into the other. These are laid upon a surface, called the *Aludel-bath*, first descending a little, and then ascending, and finally open into the chimney. [For details and figures of all these forms of apparatus, and of an improved process suggested by Dr. Ure for performing the distillation in iron retorts, see *Ure's Dictionary of Arts, &c.*, iii. 68]. Mercury is sent into the market, sometimes in leathern bags, sometimes in wrought-iron bottles, which are afterwards used in chemical laboratories for the preparation of potassium.

Purification from foreign metals.—1. The mercury is distilled either alone, or, better, under a thick layer of iron filings, in glass, earthen, or other retorts. A portion of the foreign metals is very apt to pass over with the mercury, either in the form of vapour or by spitting during the ebullition. The latter of these accidents is prevented by the coating of iron-filings. 2. By distilling the mercury with one-tenth of its weight of cinnabar, the sulphur of which retains the foreign metals. (Därfurt.)

3. By boiling the impure mercury for some hours with $\frac{1}{2}$ of its weight of mercurous nitrate dissolved in water, or with a small quantity of very dilute nitric acid, or by digesting it with either of these liquids in the cold, the mercury being placed in a shallow dish, so as to expose a large surface, and frequently agitated; or by agitating the mercury for some days with sulphuric acid—which must be stronger, as the mercury is more impure—till the acid no longer becomes turbid, or takes up any foreign substance (Branchi, *Repert. Pharm.* vi. 77).—4. Ulex (*Ann. Ch. Pharm.* lx. 210) agitates two pounds of mercury with half an ounce of solution of ferric chloride,

having a specific gravity of 1.45. The mercury is thereby reduced to a state of very fine division, and the action on the foreign metals is accelerated by the formation of chloride of mercury, which collects between the drops. It is sufficient to agitate the mercury with the iron solution for ten minutes, and then wash it with water. The mercury, after drying, is easily reunited by the application of a gentle heat.—5. A small quantity of mercury may be speedily purified by placing it in a bottle with a little finely powdered loaf-sugar, the mercury not occupying more than one-fourth of the capacity of the bottle; the bottle is then closed and briskly agitated for a few minutes, after which the stopper is withdrawn, and fresh air blown into the bottle with a pair of bellows, and the agitation is repeated; this is done three or four times, and the mercury is then poured into a cone of smooth writing paper, having a pin-hole at its apex. The metal then runs through, leaving the pounded sugar mixed with the oxides of the foreign metals, and a considerable quantity of finely divided mercury.

Pure mercury should leave no residue when dissolved in nitric acid, evaporated and ignited; or when fused with sulphur and sublimed in a glass flask. When made to run down a gently-inclined surface, it should retain its round form, and not drag a tail; and when agitated in a bottle with dry air, it should not yield any black powder.

Properties.—Mercury freezes, according to Hutchins, at $-39^{\circ}44'$, undergoing considerable contraction, and forming a tin-white, ductile mass, crystallised in octahedrons and needles, capable of being cut with a knife, and exhibiting a granular fracture. At ordinary temperatures, it forms a very coherent but very mobile liquid, which adheres but slightly to glass, and has a density of 13.5592 (Karsten), 13.5886 at 4° , and 13.535 at 26° (Kupffer), 13.568 (Cavendish and Brisson), 13.575 (Fahrenheit), 13.613 at 10° (Biddle), 13.595 at 4° (Kopp), 13.596 (Regnault). For its specific heat see HEAT (p. 30); rate of expansion (pp. 54-57); latent heat of fusion (p. 77).

Mercury remains unaltered when agitated for any length of time with oxygen gas, common air, hydrogen, nitrogen, nitrous oxide, nitric oxide, carbonic acid gas, or alcohol; but any foreign metals that may be mixed with it become oxidised by agitation in air or oxygen gas, producing a grey pulverulent mixture of the oxides of the foreign metals and finely divided metallic mercury. On the other hand, by agitation with water, ether, or oil of turpentine, or by trituration with sulphur, sulphide of antimony, sugar, grease, &c., even in vacuo, mercury is converted into a grey powder, *Aethiops per se*, consisting of small globules of the metal, which are separated by interposition of foreign matter, but run together again on its removal: this is called the *Extinction* or *Deadening of Mercury*. In well prepared grey mercurial ointment, the mercury forms nearly uniform globules, having a diameter between $\frac{1}{1000}$ and $\frac{1}{10000}$ of a line, and not distinguishable by the naked eye (Ehrenberg, Pogg. xxiv. 40). The deadening of mercury was formerly attributed to oxidation. According to Bärensprung (J. pr. Chem. 1. 21), some, at least, of the mercury in grey mercurial ointment is in the state of black oxide (the quantity being greater, the older the ointment), and this oxide, after the fat has been extracted by ether, may be dissolved out by water slightly acidulated with sulphuric acid.

Mercury boils, according to Crichton, at 346° ; according to Dalton, at 349° ; according to Heinrich, at 356° ; according to Dulong and Petit, at 360° , and is thereby converted into a colourless vapour. Vapour rises, however, from mercury, even between $+15^{\circ}5'$ and 27° (but not at $-6^{\circ}7'$), both in vacuo and in spaces filled with air, as shown by the silvering of gold-leaf, kept for two months in a vessel over mercury (Faraday, 7^o). According to Karsten (Pogg. Ann. lxxi. 245), mercury at temperatures below 0° , gives off sufficient vapour to bring out the image on a Daguerreotype plate held over it. —Brame (Institut. 1849, 403) finds that sulphur in the very finely divided utricular condition (*utricules de soufre*) in which it is first precipitated from the state of vapour, is a much more delicate test for the presence of mercurial vapour than gold-leaf. By means of this test, he finds that at 12° the vapour of mercury rises to a height of more than a metre—that even at 8° , it appears to have no limited atmosphere—that it rises, at ordinary temperatures, from amalgams and mercurial ointment—that in presence of air and sulphur-vapour, it diffuses, according to the same law as other gases—but that in presence of air and iodine-vapour, and of the vapour of iodide of mercury thereby produced, the law of diffusion appears to be different. (For the tension of mercury-vapour at different temperatures, see HEAT, p. 94.)

The density of mercury-vapour, referred to air as unity, is 6.7 (Bineau, Compt. rend. xlix. 799). The theoretical density is 100 referred to hydrogen, or 6.933 referred to air, as unity, the molecule of the vapour containing 2 at. Hg ($=100$) or 1 at. Hg ($=200$).

According to Wiggers (Pogg. Ann. 440), mercury is slightly soluble in boiling water. When twenty ounces of water are poured upon two ounces of mercury, and boiled down to ten ounces, the decanted liquid shows no particular reaction with

sulphydric acid or stannous chloride; but on mixing it with ten drops of nitric acid, and evaporating, the residue exhibits a slight brown tint when treated with sulphydric acid. Anthon also (J. pr. Chem. xv. 153) found that water boiled with mercury for fifteen hours, and then decanted, was capable of silvering gold-leaf; and after evaporation with nitric acid, gave the characteristic reactions with sulphydric acid and stannous chloride. Paton and Favrot (J. Chim. méd. xiv. 306), in repeating the experiment of Wiggers with distilled water and with river-water, did not discover mercury in the water after evaporation with nitric acid. Girardin also (J. Chim. méd. ix. 283) found no mercury in water, which had been boiled with that metal; he did not, however, mix it with nitric acid before evaporation. When water is poured upon mercury, boiled down to one-half, decanted, then left to stand for several days, again decanted, and thrown upon a thick paper filter, small quantities of mercury, sufficient to silver gold-leaf, remain on the filter; but the filtrate, when mixed with nitric acid and evaporated, shows no trace of mercury. Perhaps the quantity used in the experiment was too small; but, at all events, the experiment shows that the mere decantation adopted by Wiggers is not sufficient to separate the water from the mercury mechanically mixed with it; to decide the question completely, experiments should be made with large quantities of water. (L. Gmelin, *Handbook*, vi. 4.)

Hydrochloric acid, even when hot and concentrated, has no action upon mercury. *Nitric acid* slowly dissolves it in the cold; and, if the acid is in excess, converts it into neutral mercurous nitrate. When nitric acid is boiled with excess of mercury, the metal is converted into basic mercurous nitrate, which crystallises on cooling. If, on the other hand, the nitric acid is in excess, the whole of the mercury is converted into mercuric nitrate; mercury heated with excess of *nitromuriatic acid*, yields mercuric chloride and nitrate. Mercury is scarcely attacked by dilute *sulphuric acid*, but when heated with the concentrated acid, it is converted into solid mercuric sulphate, with evolution of sulphurous anhydride. If the sulphuric acid is small in quantity, and the heat is not raised quite to the boiling point, mercurous sulphate is obtained. *Chlorine gas* passed over gently heated mercury, converts it into mercuric chloride.

Mercury forms two series of compounds, viz. the mercuric compounds, into which 1 atom of mercury enters as a bivalent radicle, and the mercurous compounds, in which 2 atoms of mercury are linked together so as to form a bivalent radicle ($\text{Hg} \equiv \text{Hg}$); thus:

Mercuric chloride	. . .	$\text{Hg}^{\text{II}}\text{Cl}^2$	=	200 + 2 . 35.5	=	271
Mercuric oxide	. . .	$\text{Hg}^{\text{II}}\text{O}$	=	200 + 16	=	216
Mercurous chloride	. . .	$(\text{Hg}^{\text{I}})^2\text{Cl}^2$	=	2 . 200 + 2 . 35.5	=	471
Mercurous oxide	. . .	$(\text{Hg}^{\text{I}})^2\text{O}$	=	2 . 200 + 16	=	416

There are also several compounds in which mercury forms part of a base or radicle belonging to the types ammonia and ammonium, e.g. bromide of mercurammonium $\text{Hg}^{\text{I}} \left\{ \text{N}^{\text{H}}\text{Br}^2 \right.$; chloride of tetramercurammonium, $(\text{Hg}^{\text{I}})^4\text{N}^2\text{Cl}^2$. Trimercuramine, $(\text{Hg}^{\text{I}})^3\text{N}^2$, is known in the free state.

MERCURY, ALLOYS OR AMALGAMS OF. Mercury is capable of uniting with most other metals, forming compounds called amalgams, some of which are liquid, while others are solid. The solid amalgams appear to be for the most part of definite chemical constitution; while the liquid amalgams may be regarded in many instances as solutions of definite compounds in excess of mercury, inasmuch as when they are pressed between chamois leather, mercury containing but a small quantity of the other metal passes through, while a solid amalgam, frequently of definite atomic constitution, remains behind. Even in the solid amalgams, however, the affinity by which the two metals are held together is but feeble; for Joule has shown that many of those which contain equal numbers of atoms of their component metals may be partly decomposed by subjecting them to very strong pressure, part of the mercury being then forced out, and an amalgam containing a larger portion of the other metals remaining behind. In most instances also the formation of amalgams is attended with little or no contraction of volume; in the case of silver and copper, however, the contraction is considerable; and with tin, lead, and a few others, it is perceptible. The union of mercury with potassium and sodium is attended with considerable evolution of heat.

The methods of combining mercury with other metals are:

1. Bringing the mercury into direct contact with the other metal, either in the solid

disturbance, sometimes taking place at ordinary temperatures, sometimes with the assistance of heat.

The solution of metallic mercury into the solution of a salt of the other metal, and the precipitation of the latter into the solution and precipitating the other metal, are sometimes assisted with the rest of the mercury. In some cases the precipitation may be assisted by means of an amalgam of a highly electropositive metal, as, for example, a sodium-salt is then formed, and the other metal is precipitated on the mercury and unites with it.

3. The introduction of various metals into solutions of mercury-salts, copper for example. In the case of silver, gold, or platinum, which do not directly precipitate mercury from its solutions, the action must be assisted by immersing a piece of zinc or iron into the solution, and bringing it in contact with the other metal, so as to form a voltaic circuit: thus a drop of solution of mercuric chloride laid on a piece of gold will not amalgamate it; but if an iron wire or a key be placed in contact with the wetted surface of the gold, a white spot of amalgam is immediately formed at the point of contact.

4. By placing the metal to be amalgamated in contact with mercury and with a dilute acid, a voltaic circuit being also formed in this case. Thus when a zinc plate is wetted with dilute sulphuric acid, and mercury poured upon it, the zinc is immediately amalgamated.

Several amalgams are used in the arts. Tin amalgam is used for 'silvering' mirrors; amalgams of gold and silver in the processes of gilding and silvering by heat; cadmium-amalgams, copper-amalgams, and an amalgam of tin, gold, and silver, are used for stopping teeth; an amalgam of zinc and tin, sometimes with addition of bismuth, is used for coating the rubbers of electrical machines.

Aluminium-amalgam?—Klauser (Ann. Ch. Pharm. x. 391) found that potassium-amalgam laid on a lump of alum, decomposed it, the mercury taking up a considerable quantity of aluminium. Böttger (J. pr. Chem. i. 305) was not able to obtain an amalgam of aluminium in this manner; and according to Deville, metallic aluminium is not susceptible of amalgamation.

According to Cailletet (Compt. rend. xlv. 1250), aluminium (also iron and platinum) may be superficially amalgamated by contact with ammonium, or sodium-amalgam and water; also when it is immersed in acidulated water in contact with metallic mercury forming the negative pole of a voltaic battery.

Ammonium-amalgam. See i. 188.

Antimony-amalgam is said to be formed by triturating 3 pts. of heated mercury in contact with 1 part of fused antimony; or by triturating 2 pts. of antimony in a mortar with a small quantity of hydrochloric acid, and gradually dropping in 1 pt. of mercury. It is soft, and is decomposed by contact with air or water, the antimony separating in the form of a black powder.

Arsenic-amalgam.—Bergmann states that a compound containing 5 pts. mercury to 1 pt. arsenic is produced by heating and triturating the two metals together.

Barium-amalgam may be prepared by the galvanic method, or better, perhaps, by decomposing a saturated solution of chloride of barium with sodium-amalgam. It is a soft pasty mass, in which a few sandy grains may be felt. It is rapidly decomposed by water, and must therefore be kept under rock-oil.

Bismuth-amalgam.—Mercury amalgamates bismuth even at ordinary temperatures; but the amalgam is more quickly formed by pouring 2 pts. of hot mercury into 1 pt. of melted bismuth. The amalgam, which is soft at first, gradually becomes crystallo-granular. Sodium-amalgam in contact with moist neutral nitrate of bismuth, or immersed in a solution of that salt, forms a compact amalgam, with evolution of hydrogen, and separation of black pulverulent bismuth (Böttger). A small quantity of bismuth takes away but little of the fluidity of mercury, and is therefore used for adulterating that metal; according to Lucas, however (N. Trommsd. i. 195), mercury adulterated with only 1 pt. of bismuth forms a black powder when agitated in the 1000 1 pt. of bismuth dissolved even in 1,200,000 pts. of mercury may be detected by the addition of potassium-amalgam and water, the bismuth being then raised by the galvanic action in the form of a black powder, and attaching itself to the sides of the vessel (Serullas, Ann. Ch. Phys. [3] xxxiv. 192.)

Cadmium-amalgam.—Mercury combines readily with cadmium, even at ordinary temperatures, forming a silver-white granular amalgam, consisting of octahedral crystals; hard, brittle, heavier than mercury, and melting at 75°. When the mercury is completely saturated with cadmium, the amalgam contains 78.26 pts. mercury to 21.74 pts. cadmium, agreeing with the formula $Hg \cdot Cd$ (Stromeyer). Sodium-amalgam introduced into a solution of cadmium is converted into cadmium-amalgam. (Böttger.)

Calcium-amalgam.—Produced by the action of a powerful solution of hydrate of calcium in contact with mercury; also, according to Klaproth, by the action of sodium-amalgam on calcium-salts.

Cobalt-amalgam is not easily prepared by the action of sodium-amalgam on cobalt-solutions, inasmuch as a considerable quantity of cobalt-oxide is thereby precipitated. Damour immerses an amalgam of 5 pts. mercury, and 1 pt. zinc in an acid solution of cobalt-chloride supersaturated with ammonia; pours the liquid off after a few days, and decomposes it with fresh portions of zinc-amalgam as long as any gas is thereby evolved; and lastly, removes the excess of zinc by dilute sulphuric acid. The cobalt-amalgam thus obtained is silver-white, soft and dull; is attracted by the magnet even when it contains zinc (?), and becomes covered with black, pulverulent oxidised cobalt when exposed to the air.

Copper-amalgam may be formed: 1. By immersing a piece of copper-foil in a solution of nitrate of mercury.—2. By triturating mercury with common salt and verdigris.—3. By triturating 2 pts. of mercury, 2 of verdigris, and 1 of common salt with a small quantity of heated vinegar, which must be renewed as it evaporates, and purifying the amalgam by washing.—4. By mixing 1 pt. of finely-divided copper—obtained by reducing the oxide with hydrogen, or by precipitation from the sulphate by zinc or iron—with a few drops of mercurous nitrate, and then triturating with 3 pts. of mercury, a light red amalgam is formed (Berzelius).—5. Mercury placed in contact with the negative pole of a voltaic battery, and covered with solution of cupric sulphate into which the positive wire dips, becomes perfectly saturated with copper (Grove, Phil. Mag. [3] xv. 83). According to Joule (Chem. Gaz. 1850, p. 339), the amalgam thus obtained has the composition CuHg ; and the same definite compound is obtained by dissolving copper in mercury, and removing the excess of the latter by strong pressure (Chem. Gaz. 1850, p. 339). When, however, the pressure is very strong, or is continued for a long time, the resulting amalgam contains more than 1 at. Cu to 1 at. Hg (Joule, Chem. Soc. J. xvi. 382).—6. Copper amalgam may also be formed by treating a solution of cupric sulphate with sodium-amalgam (Klauser), or zinc-amalgam (Damour). Sodium-amalgam immersed in a mixture of cupric sulphate and sal-ammoniac forms a reddish or golden-yellow amalgam of copper and ammonium, which soon decomposes.—7. A copper-amalgam used by the Parisian dentists for stopping teeth is prepared by triturating mercurous sulphate (obtained by heating together 10 grms. of mercury and 10 grms. of strong sulphuric acid) and finely-divided copper (obtained by precipitating a solution of 23.5 grms. cupric sulphate in 10 or 12 times its weight of water, with metallic iron). The materials are triturated together under hot water for 20 or 30 minutes; the water then poured off, and the trituration repeated with fresh quantities of water as long as the water exhibits any blue colour. The amalgam is then dried, again triturated, then well kneaded, and formed into small cakes, which become quite hard in 36 to 48 hours. The amalgam thus produced contains 3 pts. copper to 7 pts. mercury. An easier mode of preparing it is to moisten the precipitated copper with solution of mercurous nitrate, then pour hot water upon it, and incorporate the required quantity of mercury by trituration; the mass, which is brittle at first, gradually softens under the pressure of the pestle.

This amalgam, which becomes quite hard by keeping, is distinguished by the property of softening and acquiring the consistence and elasticity of clay by continued pounding or kneading, and recovering its hard crystalline character when left to itself for a few hours; it may then be pulverised, exhibits a granulo-crystalline fracture, and is hard enough to engrave upon tin. When heated it swells up, and small globules of mercury show themselves on its surface, sinking into the mass again on cooling. On triturating the warmed lumps in a mortar, the amalgam is again obtained in the form of a highly plastic almost unctuous mass. Its density is the same in the soft as in the hard state, so that it does not expand or contract in hardening, and therefore fills cavities air-tight when hard, into which it has been pressed in the soft state. It is on account of this property that the amalgam is used for stopping teeth, but the copper which it contains renders it decidedly objectionable for that purpose. It may, however, be advantageously used for sealing bottles, glass tubes, &c., in cases where other plastic substances, cork, &c., cannot be used.

Iridium-amalgam is obtained as a semi-fluid mass by decomposing a concentrated solution of sodio-iridic chloride with sodium-amalgam.

Gold-amalgam.—See GOLD, ALLOYS OF (ii. 927).

Iron-amalgam.—Mercury and iron do not unite readily. A viscid amalgam is, however, obtained by immersing sodium-amalgam containing 1 per cent. sodium in a clear saturated solution of ferrous sulphate. In small globules it is attracted by the magnet, and when slowly heated on a watch-glass, exhibits the vivid sparkling of

burning iron (Böttger). According to Aikin, iron-amalgam is formed by the action of zinc-amalgam on ferrous chloride; but according to Damour it cannot be produced in this way. Joule (Chem. Gaz. 1859, p. 339; Chem. Soc. J. xvi. 378) has obtained amalgams of iron by the electrolysis of a solution of ferrous sulphate, the negative pole being formed of mercury. The following table exhibits the composition and physical character of the compounds thus produced.

No.	Composition.		Specific gravity.	Remarks.
	Mercury.	Iron.		
1.	100	0.143	. .	Perfectly fluid.
2.	"	1.39	. .	Fluid.
3.	"	2.97	. .	Semi-fluid.
4.	"	11.8	12.19	Soft.
5.	"	18.3	. .	Solid: colour, greyish-white.
6.	"	47.5	. .	Solid: good metallic lustre.
7.	"	127.6	10.11	Solid: friable.
8.	"	14.74	. .	{ The superfluous mercury pressed out from the semi-fluid amalgam by hand.
9.	"	79	. .	{ Compressed rapidly, and with a force of fifty tons on the square inch.
10.	"	103.2	. .	Ditto.

Lead-amalgam.—See LEAD, ALLOYS OF (p. 534).

Magnesium-amalgam.—Magnesium combines with mercury only when heated, and forms a solid amalgam, even with large quantities of the latter (Bussy).—2. The amalgam may also be obtained by electrolysis.—3. By covering potassium or sodium-amalgam with solution of sulphate of magnesium (Klauser, Ann. Ch. Pharm. x. 89).—The amalgam thus obtained oxidises slowly in pure water, quickly in acidulated water. (H. Davy.)

Manganese-amalgam is obtained by the action of sodium-amalgam on a strong solution of manganous chloride. It is viscid, with rough blackish surface, and when heated in contact with the air, gives off mercury, tarnishes, is converted into a stiff paste, and finally leaves brown manganoso-manganic oxide.

Nickel-amalgam is obtained like cobalt-amalgam. It is solid; is attracted by the magnet; decomposes when exposed to the air, the nickel gradually oxidising till nothing but mercury is left; may be mixed with a larger quantity of mercury; gives up its nickel to hydrochloric and dilute sulphuric acid.

Osmium-amalgam is formed, according to Tennant, by decomposing aqueous osmic acid with metallic mercury; it is more or less fluid, according to the proportion of mercury contained in it.

Palladium-amalgam is formed by agitating the solution of a palladium-salt with excess of mercury. The amalgam containing Pd²Hg is a grey powder, which, according to Berzelius, does not give off its mercury below a white heat.

Platinum-amalgam.—Platinum in the compact state does not take up mercury, but spongy platinum unites with it when the two are triturated together, in a warm mortar, or in contact with a small quantity of acetic acid. The amalgam of platinum is easily formed by immersing sodium-amalgam containing 1 per cent. sodium in a concentrated solution of platinum chloride; sodium-amalgam also converts chloroplatinate of ammonium into platinum-amalgam, with evolution of ammonia and hydrogen. The amalgam is silvery, and does not give off mercury below a bright red heat.

Joule (Chem. Soc. J. xvi. 384), by electric deposition of platinum on mercury, has obtained amalgams exhibiting the following composition and characters:

Mercury.	Platinum.	Specific gravity.	Characters.
100	15.48	14.29	Metallic lustre where rubbed.
"	21.6	"	Solid. Dark grey.
"	34.76	14.69	Dark grey; no metallic lustre.

An amalgam of 12 platinum to 100 mercury has a bright metallic lustre, and is soft and greasy to the touch. Pressed with a force of 12 tons to the square inch, it leaves a hard button of dark grey amalgam containing 43.2 pts. platinum to 100 mercury. Joule infers from these results that the solid amalgam of platinum containing the

largest quantity of mercury has the composition PtHg^1 . A thick paste amalgam of platinum may be obtained by exposing mercury for some time to the action of platinum chloride.

Potassium-amalgam.—1. The two metals unite even at ordinary temperatures, the combination being attended with great evolution of heat (H. Davy). 2. When mercury is placed in a cup connected with the negative pole of a voltaic battery of at least 20 pairs, and covered with a strong solution of potash in which a piece of hydrate of potassium is immersed, and into which the positive wire dips, the mercury takes up potassium (Berzelius). 1 pt. of potassium forms with 30 pts. of mercury an amalgam which, after cooling, is tolerably hard and brittle; with 70 pts. mercury it likewise forms an amalgam which is solid at ordinary temperatures, but with more than 70 pts. it forms a liquid amalgam (H. Davy). According to Gay-Lussac and Thénard, the amalgam is solid and crystalline when it contains from 70 to 96 pts. of mercury to 1 pt. of potassium, but liquid when the proportion of mercury amounts to 140. According to Böttger (J. pr. Chem. i. 303), the amalgam is perfectly solid when it contains 100 pts. of mercury to 1 pt. of potassium; with 140 mercury, it is very hard; with 180 mercury, friable and partly crystallised; with 200 mercury, viscid. The amalgam crystallises in cubes (Berzelius and Pontin). The solid amalgam fuses when slightly heated. It gives off its mercury below a red heat (H. Davy). When exposed to the air or immersed in water, it is resolved into mercury and aqueous potash, hydrogen gas being slowly evolved; a similar change is produced by aqueous acids. In contact with moist ammoniacal salts, it is resolved into a potassium-salt and ammoniacal amalgam. It easily gives up its mercury to iron and platinum. (H. Davy.)

Silver-amalgam.—A native compound of mercury and of silver, called 'amalgam' by mineralogists, and having the composition Ag^2Hg^2 or Ag^2Hg^1 , is found crystallised in octahedrons, rhombic dodecahedrons, and other forms of the regular system, with dodecahedral cleavage in traces; also massive. Hardness = 3 to 3.5. Specific gravity = 10.5 to 14. Colour and streak silver-white; opaque; fracture conchoidal; brittle, and gives a grating sound when cut with a knife. Klaproth found in amalgam from Moschellandsberg in the Palatinate, 36 per cent. silver and 64 mercury, agreeing with the formula Ag^2Hg^2 . Hoyer, on the other hand, found in amalgam from the same locality, only 25 per cent. silver, agreeing with AgHg^1 ; and a specimen from Allevard in Dauphiné, analysed by Cordier, exhibited nearly the same composition, viz. 27.5 per cent. silver. Amalgam also occurs at Rosman in Hungary, Sala in Sweden, Almaden in Spain, and in Chile. A native silver-amalgam called *Arguerite*, occurring in crystals at Arqueros, Chile, contains, according to Doneyko, 13.5 per cent. silver, and 86.5 mercury, giving the formula Ag^2Hg^2 .

Mercury is taken up by silver slowly at ordinary temperatures, but quickly when the metal, in the form of a thin lamina, or in powder, is introduced at a red heat into heated mercury. Metallic mercury immersed in a solution of silver-nitrate, precipitates the silver in the form of a crystalline amalgam, called a silver tree, or *Arbor Dians*. The silver-solution should be somewhat acid, and not too much concentrated. A soft silver-amalgam is formed by the action of sodium-amalgam on a strong solution of silver-nitrate.

Artificial silver-amalgam varies in character, according to its composition and the circumstances of its formation, being sometimes a soft, or crystalline, or granular mass; sometimes consisting of ramifications of prismatic crystals placed end to end. Joule finds that the amalgam most readily formed by the action of mercury on nitrate of silver has, on the average, the composition Ag^2Hg . When the action is assisted by making the mercury the negative pole of a voltaic battery, amalgams richer in silver are obtained. The mean composition of the amalgam, after being subjected to a pressure of 72 tons on the square inch, was 43.71 silver to 100 mercury. The combination of mercury and silver is attended with a considerable contraction of volume.

Sodium-amalgam.—Sodium combines rapidly with mercury at ordinary temperatures, the combination being attended with a hissing noise and vivid combustion (Gay-Lussac and Thénard, *Recherches*, i. 246). A piece of sodium forcibly thrown upon mercury, is thrown out of the vessel with explosion, in consequence of the great heat produced (Serullas, *Ann. Ch. Phys.* [2] xl. 328). To form the amalgam, the two metals should be triturated together in a dry mortar fitted with a cover, and the mixture immersed in rock-oil as soon as the combustion is over (Böttger). The amalgam has the colour of mercury. When it contains 30 pts. of mercury to 1 pt. of sodium, it is tolerably hard under the file, which wears it away in the form of powder; it exhibits a crystalline, laminar fracture. When it contains 40 pts. of mercury, it is still solid, but softer than with 30 pts. (Lampadius). An amalgam containing 60 pts. of mercury to 1 pt. of sodium forms a stiff paste at 21° (Böttger). 64 pts. of

mercury and 1 of sodium form a compound which exhibits a confused crystalline structure (Gay-Lussac and Thénard). 80 pts. mercury to 1 sodium: pasty at 21° (Böttger). 86 mercury to 1 sodium: a mass containing numerous small granular crystals (Gay-Lussac and Thénard). 100 mercury to one sodium: viscid, and consisting of a solid and a liquid portion (Böttger). 128 mercury to 1 sodium: liquid (Gay-Lussac and Thénard). Sodium-amalgam exhibits the same reactions as potassium-amalgam. It likewise amalgamates iron and platinum (H. Davy). It decomposes the salts of barium and strontium, and many heavy metallic salts, when a small quantity of water is present, the product being a compound of mercury with the heavy metal (Böttger, J. pr. Chem. iii. 283). It is now much used as a reducing or hydrogenating agent for effecting the substitution of hydrogen for chlorine, bromine, &c., in organic compounds.

Amalgam of Potassium and Sodium.—5 pts. potassium and $\frac{1}{2}$ pt. sodium melted together by heating them under rock-oil, form an alloy which is fluid like mercury at 9° , but when brought in contact with 100 pts. of mercury, unites therewith into a very solid mass. (Böttger.)

Strontium-amalgam.—Prepared like that of barium, which it resembles, but decomposes more quickly under a mixture of the solutions of chloride of strontium and chloride of calcium, as well as under water. When exposed to the air for eight or ten hours, it is converted into carbonate of strontium, with separation of mercury.

Tellurium-amalgam.—Mercury and tellurium are said to unite directly, forming a tin-coloured amalgam.

Thallium-amalgam.—The two metals unite readily, forming a crystalline amalgam. (Crookes.)

Tin-amalgam.—Mercury and tin unite quickly, even at ordinary temperatures, still more quickly on pouring mercury into melted tin. A piece of tin, the lower end of which is immersed for four weeks in mercury, is penetrated through and through by the mercury, and exhibits cracks; its lower end becomes attenuated by solution of the metal, and the immersed part is found to be covered with six-sided tables, some of which float about in the mercury. If a square bar of tin, whether cast in a square form, or hammered or filed square from a round bar, be kept for a few days under mercury, it splits in directions proceeding from the lateral edges to the opposite diagonals, thereby dividing itself into four triangular prisms, easily separated by a knife; at the same time, a four-sided pyramid is formed at each end of the square bar. If the piece of tin has any other form, cracks are produced in other directions (Daniell, J. of Roy. Inst. i. 1). Sodium-amalgam immersed in a concentrated solution of stannous chloride, yields a viscid amalgam of tin. (Böttger.)

Tin-amalgam has a tin-white colour; and if the mercury is not in too great excess, is brittle, granular, and according to Daubenton, crystallises in cubes.

Sn^2Hg and SnHg do not fuse till heated above 100° . (Regnault.)

Sn^2Hg has at 26° a specific gravity of 8.8218; Sn^2Hg , 9.3185; SnHg , 10.3447; SnHg^2 , 11.3816. 1 vol. of tin with 1 vol. of mercury forms an alloy whose specific gravity at 27° is 10.4729; 1 vol. tin with 2 vol. mercury, 11.4646; and 1 vol. tin with 3 vol. mercury, 12.0257. In most cases, therefore, condensation takes place; in the single instance of 1 vol. tin to 2 vol. mercury, however, this condensation is scarcely perceptible. (Kupffer, Ann. Ch. Phys. [2] xl. 293.)

The compound obtained by fusing 4 pts. of tin with 1 pt. of mercury, yields, if pulverised after cooling, a kind of mosaic silver, which, when rubbed on the polishing-stone, acquires the metallic lustre. The *silvering of mirrors* is likewise an amalgam of tin.

Joule obtained beautiful crystalline amalgams by making mercury negative in a solution of stannous chloride. The amalgam containing 100 mercury to 51 pts. tin, had a specific gravity of 10.518; that containing 100 mercury to 44.1 tin, a specific gravity of 10.94: hence the combination is attended with contraction of volumes. The amalgam of tin is decomposed by pressure, the mercury left after long-continued high pressure having a volume little more than one-eighth of the entire mass.

An amalgam of tin and bismuth is obtained by melting together 2 pts. of tin, 2 pts. of bismuth, and 1 pt. of mercury.

An amalgam of 2 pts. tin and 1 pt. cadmium is used for stopping teeth. The two metals are melted in an iron ladle, slightly warmed; mercury is added; the whole is poured into an iron mortar, and rubbed with a wooden pestle, till it acquires a soft buttery consistence; and the excess of mercury is squeezed out through leather. The residue is almost granular, but becomes soft and plastic when kneaded by the hand.

An amalgam of tin and lead may be formed by introducing an alloy of the two metals into mercury.

Amalgams containing tin, lead and bismuth are described under LEAD (p. 537). An

amalgam of 8 pts. bismuth, 5 lead, 3 tin, and 7 or 8 mercury is recommended by Brame for coating the rubbers of electrical machines.

An amalgam of *tin, silver and gold* is also used as a cement for the teeth. It is prepared by melting together 1 pt. gold and 3 pts. silver, adding 2 pts. tin to the melted mass, pulverising the resulting alloy, and kneading it together with an equal weight of mercury.

Zinc-amalgam.—When zinc-filings are triturated with mercury, at ordinary temperatures, combination takes place slowly; at a higher temperature, still somewhat under the boiling point of mercury, the metals combine easily, and still more readily when mercury is mixed with melted zinc. A bar of zinc, immersed to half its length in mercury for ten days, becomes pointed at bottom, and covered, especially on the upper part of the immersed end, with six-sided tables of the amalgam (Daniell). When zinc is placed in contact with mercury and a dilute acid, a galvanic action is set up (ii. 420), and the zinc becomes covered with mercury, which then penetrates into the interior, and converts the whole of the metal into an amalgam. As soon as the zinc is completely covered with mercury, the evolution of hydrogen ceases; but it begins again on bringing the amalgam in contact with iron, copper, or platinum, to which metals the mercury is then transferred (Döbereiner). Sodium-amalgam immersed in a concentrated solution of sulphate of zinc, forms a viscid amalgam of zinc. (Böttger.)

The amalgam is usually prepared by cooling melted zinc to as low a temperature as it will bear without solidifying, and then pouring in the mercury in a fine stream, keeping the liquid constantly stirred. If this precaution be neglected, part of the mercury is converted into vapour, sometimes throwing the melted metal about.

8 pts. zinc to 1 pt. mercury: very brittle.

1 pt. zinc and 4 or 5 pts. mercury form an amalgam sometimes used for coating the rubbers of electric machines; it is brittle and pulverulent.

1 pt. zinc to 6 pts. mercury: tin-white, granular, brittle; melts at the boiling point of olive-oil, but does not give off mercury till raised to a higher temperature. At a dull red heat, it decrepitates strongly; at a stronger red heat, it burns with great brilliancy. It is permanent in dry air. Cold dilute nitric acid decomposes it readily, and leaves the mercury unaltered till all the zinc is dissolved. Dilute sulphuric and hydrochloric acid act on it but slowly. Ammonia and sal-ammoniac also dissolve out the zinc very slowly, and form water. Zinc-amalgam immersed in the solution of a neutral salt of chromium, uranium, manganese, or iron, merely throws down the oxide; but from neutral solutions of cobalt, nickel, and copper, it precipitates the metal, which then combines with the mercury. (Damour, *Ann. Min.* [3] xv. 41; also *J. pr. Chem.* xvii. 345.)

From an amalgam richer in mercury, six-sided laminae containing 2 pts. zinc and 5 mercury, separate out on cooling. The portion which remains liquid is a solution of zinc in excess of mercury. 1 pt. of zinc dissolved in 8,000 pts. of mercury may be detected by the black powder which forms on the surface when the mercury is agitated in contact with the air.

Zinc-amalgam immersed in caustic potash liberates pure hydrogen. When zinc-amalgam is immersed in aqueous ferrous chloride, and a crystal of a nitrate is placed upon it, a black spot is gradually formed on the surface of the amalgam, consisting of reduced iron, which is immediately taken up by the mercury. The presence of a nitrate is essential to the production of this effect; chlorates and other salts do not produce it. (Runge, *Pogg. Ann.* ix. 479.)

Joule, by the electrolytic method, has obtained amalgams of zinc having the following composition and properties:

Mercury.	Zinc.	Specific gravity.	
100	39.4	11.31	White and crystalline.
"	122.8	8.935	"
"	134.9	8.349	Prepared from hot sulphate of zinc.

The specific gravity of the first of these amalgams indicates a certain contraction of volume. Pressure appears to decompose it, mercury being expelled till the amalgam consists of about 1 at. Hg to 3 at. Zn.

Amalgams of *tin and zinc* are used for coating the rubbers of electrical machines. Kienmayer recommends as the best proportion: 1 pt. zinc, 1 pt. tin, and 2 pts. mercury. Singer recommends 2 pts. zinc, 1 pt. tin, and 3½ to 6 pts. mercury.

MERCURY, ANTIMONIDE OF. See page 886.

MERCURY, ARSENIDE OF. See page 886.

MERCURY, BROMIDES OF. Mercury forms two bromides, distinguished as *mercurous* and *mercuric*.

a. Mercurous Bromide. $(\text{Hg}^2)\text{Br}^2$.—This compound is formed: 1. By subliming an intimate mixture of 1 at. mercury and 1 at. mercuric bromide (Löwig).—2. By precipitating mercurous nitrate with aqueous bromide of potassium (Balard). When prepared by the first process, it forms a fibrous mass (Löwig); long needles which are yellow while hot, but become whitish on cooling (O. Henry, J. Pharm. xv. 56). By (2): white powder (Balard); yellowish-white flakes (O. Henry). Specific gravity 7.307 (Karsten). It is tasteless and inodorous; fusible, and volatilises undecomposed at a low red heat.

When heated with *phosphorus*, it is resolved into bromide of phosphorus and phosphide of mercury (Löwig). Treated with cold aqueous *ammonia*, and then washed with water containing ammonia, it leaves a grey powder, which contains globules of mercury, and when heated, gives off ammonia, and yields a sublimate of mercury, mercurous bromide, and mercuric bromide (Rammelsberg). With caustic *potash*, it yields mercurous oxide and bromide of potassium. When boiled with aqueous *bromide* or *chloride of ammonium*, it yields a solution of mercuric bromide, with a residue of metallic mercury (Löwig). It is not perceptibly soluble in cold *carbonate*, *chloride*, or *succinate of ammonium*, while the same liquids, when hot, dissolve it with tolerable facility, leaving, however, a grey-pulverulent residue [metallic mercury]; it is not perceptibly soluble in *sulphate* or *nitrate of ammonium*, even at the boiling heat. (Wittstein.)

B. Mercuric Bromide. Hg^2Br^2 .—1. Mercury unites with bromine at ordinary temperatures, forming this compound, the combination being attended with evolution of heat, but not of light (Balard).—2. The same compound is formed by agitating mercury with water, adding bromine as long as its colour is destroyed, then boiling, filtering, and leaving the solution to crystallise.—3. By dissolving mercuric oxide in hot aqueous hydrobromic acid, and leaving the solution to crystallise.—4. By subliming mercuric sulphate with bromide of potassium (Löwig). The sublimate contains also mercurous bromide (O. Henry).—5. By mixing aqueous mercuric nitrate with bromide of potassium, evaporating as long as bromide of mercury crystallises out, and purifying the product by solution in alcohol. The mother-liquid evaporated to dryness leaves a residue, from which boiling alcohol still extracts a small quantity of the compound. (Löwig.)

Mercuric bromide crystallises from the aqueous solution in soft, silvery laminæ; from the alcoholic solution in white needles (Löwig). According to Handl (Jahresh. 1859, p. 226), the crystals are rhombic prisms, ∞P , ∞P , cleavable parallel to ∞P , and having the angles $\infty\text{P} : \infty\text{P} = 68^\circ 24'$ and $111^\circ 26'$. They are isomorphous with sublimed mercuric chloride. The product obtained by (5) has, after drying at a strong heat, a specific gravity of 5.9202 (Karsten). Mercuric bromide melts and sublimates when heated. It dissolves in 94 pts. *water* at 9° (Lassaigne) and in 4 pts. of boiling water, the greater part separating as the liquids cool. The aqueous solution reddens litmus. It dissolves very easily in *alcohol*, still more in *ether*.

With *phosphorus* it forms bromide of phosphorus. Heated with *antimony* or *arsenic*, it gives up its bromine. Its aqueous solution exposed to *sun-light*, or placed in contact with *mercury* or *copper*, or mixed with *cuprous bromide* dissolved in hydrobromic acid, deposits mercurous bromide. With a small quantity of *sulphydic acid* it yields a white, and with a larger quantity a black precipitate (H. Rose). With *ammonia* it forms a white, with fixed *alkalis* a yellow precipitate (Löwig). *Hypochlorite of sodium* added to the solution throws down mercuric oxychloride (Rammelsberg), and hypochlorous acid converts mercuric bromide into mercuric chloride and bromate, the action being attended with evolution of chlorine and bromine (Balard). Heated with *nitric* or *sulphuric acid*, it gives off vapour of bromine (Balard); but according to H. Rose (Analyt. Chem.) it is not decomposed by sulphuric acid.

Double Salts of Mercuric Bromide.—Mercuric bromide unites with the more basic metallic bromides, forming easily soluble double salts (called by Bonsdorff, bromohydrargyrites), losing thereby its power of reddening litmus. Those containing the bromides of the alkali-metals are crystallisable.

Ammonium-salt.—Mercuric bromide dissolves abundantly in aqueous bromide of ammonium. Alkaline carbonates added to the solution throw down bromide of dimercurammonium. (Löwig.)

The **barium-salt** crystallises in highly lustrous prisms, which deliquesce in moist air. (Bonsdorff.)

Calcium-salt.—A solution of bromide of calcium saturated with mercuric bromide

yields by spontaneous evaporations; at first tetrahedrons and octahedrons, which have a strong lustre, are permanent in the air, and are decomposed by a small quantity of water, but dissolve completely when heated and crystallise out again on cooling. If the evaporation be carried further, prisms or needles are obtained, which deliquesce even in dry air. (Bonsdorff.)

The *iron-salt* [? ferric or ferrous] forms yellowish very deliquescent prisms. (Bonsdorff.)

Magnesium-salts.—A solution of mercuric bromide and bromide of magnesium yields, by evaporation over oil of vitriol, first broad thin laminae, permanent in the air and probably containing MgHg^2Br^2 ?, then very deliquescent crystals containing MgHgBr^2 . (Bonsdorff.)

The *manganese-salt* crystallises in light red very hygroscopic prisms.

Potassium-salts.—A solution of the salt KHg^2Br^2 or $\text{KBr.Hg}^2\text{Br}^2$ is obtained by saturating a cold moderately concentrated solution of bromide of potassium with mercuric bromide, in anhydrous yellow octahedrons (Löwig), in flat rhombic prisms permanent in the air and containing 1 at. water. The crystals melt when heated, and yield a sublimate of mercuric bromide (Löwig). A solution of equal parts of this salt and bromide of potassium yields the salt K^2HgBr^2 (?) in prisms which are permanent in the air. (Bonsdorff.)

The *sodium-salt* crystallises partly in needles, partly in rhombic prisms, and deliquesces in moist air.

Strontium-salts.— α . SrHgBr^2 or $\text{SrBr}^2.\text{HgBr}^2$ forms crystals soluble in water in all proportions.— β . SrHg^2Br^2 or $\text{SrBr}^2.2\text{HgBr}^2$. A solution of 1 at. bromide of strontium in twice its weight of water, takes up at 50° , 3 at. mercuric bromide, and the solution on cooling deposits 1 at. mercuric bromide and then yields small crystals of the salt β . (Löwig.)

The *zinc-salt* crystallises in prisms and tables deliquescent in moist air. (Bonsdorff.)

MERCURY, CHLORIDES OF. Mercury forms two chlorides, analogous to the bromides.

Mercurous Chloride. $(\text{Hg}^2)\text{Cl}^2$.—*Hemichloride, Dichloride, Subchloride, Protochloride, Submurate of mercury; Calomel; salzaures Quecksilberoxydul, versüßter Sublimat, versüßtes Quecksilber, Kalomel; Chlorum hydrargyri, Hydrargyrum muraticum mite, Mercurius dulcis, s. kalomelanicus, s. loticus, Draco mitigatus, Aquila mitigata, s. alba, s. celestis, s. Mercurii, Panacea mercurialis, s. celestis, s. Mercurii; Protochlorure de mercure.*

This compound is found native, as *horn-quicksilver*, in dimetric crystals exhibiting the combination $\text{P} : \infty\text{P} \infty$, like figure 227 (ii. 135), also with ∞P , $\text{P} \infty$ and oP . Length of principal axis = 1.744; $\text{P} : \text{P}$ in the terminal edges = $98^\circ 7'$; in the lateral edges = $135^\circ 56'$. It occurs also in crystalline coats and granular. Hardness = 1 to 2. Specific gravity = 6.482. It has a dirty white colour and adamantine lustre, yellow when scratched; translucent in thin splinters. Sectile. Fracture conchoidal. It is found, with cinnabar, at Moschellandsberg in the Palatinate, also at the quicksilver mines of Idria and Almaden, and at Horowitz in Bohemia.

Mercurous chloride is produced: 1. By the direct combination of mercury and chlorine, slowly at ordinary temperatures, more quickly at the boiling heat of mercury, the combination being then attended with a yellowish red flame, and mercuric chloride being likewise formed.—2. By heating mercuric chloride with metallic mercury.—3. By the action of sulphurous acid and other reducing agents on mercuric chloride.—4. By agitating mercury with a solution of ferric chloride, the action being accelerated by the presence of free hydrochloric acid.—5. By the action of hydrochloric acid on mercurous oxide, or by precipitating a mercurous salt with a soluble chloride.

Preparation.—Mercurous chloride in the pulverulent form, called *calomel*, is extensively used in medicine. It may be prepared either in the dry or in the wet way.

a. In the dry way.—1. By triturating 4 pts. (1 at.) of mercuric chloride with 3 pts. (1 at.) of mercury, the mixture being moistened with water or alcohol, and the trituration continued till the mercury has lost its fluidity—then gradually heating the mixture in a glass flask or retort till it sublimes. A large portion of the mercuric chloride is converted into calomel during the trituration. Trautwein heats the deadened mixture, gently at first, for a few hours, and pulverises it once more before sublimation. 2. By subliming an intimate mixture of equal parts of mercurous sulphate and common salt:

Planche (Ann. Chim. lxxi. 168) triturates 8 pts. of mercury, 18 pts. of dry monobasic mercuric sulphate, and 6 pts. of water, till the fluidity of the metal is destroyed, and

heats the resulting mercurous sulphate with an equal weight of common salt, till a sublimate is obtained.—3. By deadening 2 at. mercury with 2 at. common salt and 1 at. peroxide of manganese, and heating the mixture to sublimation with 2 at. sulphuric acid:

4. By trituration mercury with common salt, ferric sulphate, and a small quantity of water, till the metal has lost its fluidity, and subjecting the mixture to sublimation. (Schaffhäutl), *Ann. Ch. Pharm.* xliii. 26.) The basic ferric sulphate, often occurring as a waste product, may be made available for this process; a small quantity of ferric chloride may sublime together with the calomel (Schaffhäutl). The reaction is probably:

The calomel set free in the form of vapour by either of these processes (1—4), is either allowed to collect in the form of a dense, fibrous sublimate, and the product carefully pulverised; or the calomel vapour is cooled under such circumstances that it solidifies in the form of a soft powder instead of a solid cake. This object is attained, according to Jewel and O. Henry (*J. Pharm.* viii. 545), by causing the calomel vapour to pass into a chamber into which vapour of water is injected on the other side. According to the process now adopted in this country, on the other hand, the calomel, or the ingredients from which it is prepared, is heated in a cast-iron cylinder 2½ feet long and 1 foot wide, one end of which is provided with an opening serving to introduce and remove the materials, and closed during the operation, while the other end terminates in a contracted neck which opens into the upper part of a brick chamber, 4 feet long and broad, and 6 feet high. In this chamber the calomel condenses in the form of a soft powder. As the iron of the tube decomposes a portion of the calomel, a small quantity of mercuric chloride is added to the mixture (Calvert, *J. Pharm.* [3] iii. 121). Soubeiran (*J. Pharm.* xxix. 502) adopts the same process, excepting that he heats the materials in an earthen retort, and uses a large earthen vessel as a condensing chamber. The pulverulent calomel obtained by either of these processes is washed with a large quantity of warm water, or a small quantity of warm alcohol, to free it from the corrosive sublimate with which it is usually contaminated.

6. *In the wet way.*—1. By precipitating a warm dilute solution of mercurous nitrate with excess of common salt or sal-ammoniac, and washing the precipitate thoroughly with cold water. The calomel obtained by this process, first proposed by Scheele, is in the form of a remarkably fine powder, and has consequently somewhat more active medicinal properties than the ordinary preparation. Its more energetic action may perhaps be partly due to an admixture of basic mercurous nitrate, or mercuric oxide, which, according to Buchner, Mialhe, and others, are sometimes found in it. This admixture, however, does not occur if the solution of mercurous nitrate be largely diluted, and, if necessary, filtered, before being mixed with the soluble chloride, and if the common salt or sal-ammoniac be added in excess, and the liquid heated for some time in contact with the precipitate. To the same end, Sefström, Geiger, and Trautwein (*Repert. Pharm.* xi. 72; xii. 155) recommend that a little tartaric acid be added to the mercurous solution before mixing; and Chenevix advises the addition of hydrochloric acid to the solution of common salt. In that case, however, the liquid must not be heated so much, as, otherwise, part of the calomel will be redissolved in the form of mercuric chloride. According to Dumas, the calomel obtained by the use of common salt always contains more or less of that substance, and cannot be freed from it by washing; the presence of the salt renders the calomel thus prepared more soluble than that obtained by sublimation; but Mialhe (*J. Pharm.* xxii. 586) found only traces of common salt, and no difference in the solubility.—2. Sulphurous acid gas, evolved by heating sulphuric acid with charcoal, is passed into a solution of mercuric chloride saturated at 50°. The reaction is as follows:

The filtered liquid still contains a certain quantity of undecomposed mercuric chloride, and, therefore, still gives a precipitate of calomel when heated with sulphurous acid to the boiling point (Wöhler, *Ann. Ch. Pharm.* xc. 124). According to Sartorius (*ibid.* xvi. 325), the decomposition is almost complete in the first instance, provided the solution is sufficiently dilute (1 pt. mercuric chloride to 80 water) and the liquid saturated with sulphurous acid is heated for some time to 70° or 80°. Calculation requires a product of 84 per cent.; experiment gave 84·6 per cent.

Impurities and Adulterations.—1. *Mercuric chloride:* Cold water or alcohol agitated with the powder for some time and then filtered, turns brown on the addition of

sulphydic acid, &c. 2. *Basic mercurous or mercuric nitrates*: Red fumes evolved on heating the substance in a flask or tube till it sublimes. 3. *Metallic mercury*: Grey colour; globules of mercury discernible under the microscope. 4. *Pounded heavy spar* and similar impurities remain behind on sublimation. 5. *Gum* and other organic substances: Empyreumatic odour on the application of heat; solubility in water or alcohol, &c.

Properties.—Sublimed calomel crystallises in dimetric forms like the native mineral, but the prisms are generally united in fibrous masses. Specific gravity of the artificial product, 6.9920 (Karsten); 7.140 (P. Boullay). Vapour-density, according to Mitscherlich's observation, 8.35; by calc. for HgCl_2 , $8.25 \left(= \frac{200}{2} + \frac{35.5}{2} \times 0.0693 \right)$.

It is dirty white, translucent, and has a very high refractive and dispersive power; it acquires a transient yellow colour when heated in the state of powder. Precipitated calomel is a white, heavy powder, with a tinge of lemon-yellow. Calomel volatilises below a red heat, without previous fusion. According to Faraday, it does not volatilise at ordinary temperatures. It is tasteless and inodorous, and may be regarded as quite insoluble in water; for, according to Pfaff, a perceptible precipitate is produced in a solution of mercurous nitrate by hydrochloric acid diluted with 250,000 pts. of water.

Decompositions.—1. Calomel becomes dark grey on exposure to light.—2. Heated in a current of *phosphorus-vapour*, it yields phosphite of mercury and trichloride of phosphorus (H. Davy). 3. When heated with a small quantity of *sulphur*, it yields cinnabar and mercuric chloride; with a larger quantity of sulphur, the products are cinnabar and chloride of sulphur:

4. When immersed in cold aqueous *sulphurous acid*, it turns grey, and in the same liquid at the boiling heat it becomes greyish-black, from loss of chlorine. In this greyish-black powder, no metallic mercury can be discovered with the lens; but when heated, it is resolved into calomel and metallic mercury; it is probably, therefore, a subchloride (A. Vogel).—5. Calomel gives up its chlorine to many *metals*, both in the dry and in the wet way. On boiling it with *copper* and water, a green solution is quickly formed, and the copper becomes covered with a black film, from which hydrochloric acid extracts cupric oxide, leaving a residue of metallic mercury (A. Vogel, J. pr. Chem. viii. 107).—6. By aqueous *stannous chloride*, it is reduced to the metallic state, after some time at ordinary temperatures, but quickly on boiling (A. Vogel, Kastn. Arch. xxiii. 78).—7. With *trisulphide* (*mineral kermes*) or *pentasulphide of antimony*, it is gradually converted into black sulphide of mercury and trichloride of antimony.—8. Calomel triturated with *iodine* and water, yields mercuric chloride, which dissolves, and mercuric iodide, of which the water takes up a small portion. (Planché and Souberain, J. Pharm. xii. 651.)

9. Calomel digested in aqueous solutions of the *iodides of the alkali metals*, *magnesium chloride*, or *iron*, yields dark green mercurous iodide, and an aqueous metallic chloride. The mercurous iodide thus produced remains unchanged for a long time in the dark; but when exposed to light it first becomes yellow, and then red from loss of mercury—fuses into a black-brown liquid—gives off mercury and mercuric iodide—and leaves a white residue of metallic chloride, together with the excess of metallic iodide employed (Laboure, J. Pharm. iv. 329). 10. Hot *nitric acid* dissolves calomel, with evolution of nitric oxide gas, forming a solution of mercuric chloride and mercuric nitrate:

Cold *sulphuric acid* neither dissolves nor decomposes calomel, even after a long time; but hot sulphuric acid dissolves it (the liquid solidifying to a white saline mass on cooling), giving off sulphurous anhydride, yielding a sublimate of mercuric chloride, and leaving a residue of mercuric chloride mixed with mercuric sulphate. (A. Vogel.)

11. Calomel immersed in aqueous *hydrocyanic acid* yields metallic mercury and a liquid which contains cyanide of mercury and hydrochloric acid (Scheele, Opusc. ii. 195). Part of the calomel, however, remains undecomposed, or, at least, undissolved, even when an excess of hydrocyanic acid is present; the undissolved portion is not metallic mercury, but a black powder which, when heated, gives off calomel vapour, together with a small quantity of permanent gas, and leaves a carbonaceous powder

(Soubeiran, J. Pharm. xv. 523). The decomposition by hydrocyanic acid must therefore be more complicated than that which would be expressed by the equation:

and deserves further examination; to the medical practitioner, it is important to know that the mild substance calomel is converted by hydrocyanic acid into a compound which acts so violently as cyanide of mercury.—12. Calomel heated with dry *fixed alkalis*, yields mercury, oxygen gas, and a chloride of the alkali-metal:

By *aqueous fixed alkalis* it is converted into black mercurous oxide, a chloride of the alkali-metal remaining in solution. Calomel likewise blackens when immersed in aqueous *ammonia*, not, however, by conversion into mercurous oxide, but into chloride of mercurousammonium (NH_4HgCl). The supernatant ammoniacal liquid contains a small quantity of mercury in solution. *Carbonate of ammonium* colours calomel grey and quickly dissolves it, with the exception of a small grey residue of metallic mercury. *Carbonate of magnesium* exerts no action in the cold, even in the presence of water; but at the boiling heat, carbonic anhydride is evolved, mercury separated, and a solution formed, containing mercuric oxide in combination with magnesia (Buchner, Repert. Pharm. iii. 31; iv. 289). According to A. Vogel, Jun. (Repert. Pharm. [3] i. 34), calomel heated with water and *carbonate of calcium* (or *magnesium*) is converted into mercurous (and mercuric?) oxide and metallic mercury, carbonic anhydride being evolved and chloride of calcium formed. The carbonates of *barium* and *strontium* act in a similar manner, but not so strongly. When calomel is boiled with pounded *gypsum*, chloride of calcium and mercuric sulphate are formed; a similar effect is produced by boiling with *sulphate of sodium*.—13. By *aqueous vapour* and *boiling water*, calomel is partly converted into metallic mercury, or into a grey compound of calomel with excess of mercury and soluble mercuric chloride.—14. Boiling *hydrochloric acid* quickly converts calomel into mercuric chloride and metallic mercury. On the other hand, when water containing hydrochloric acid is boiled in an open vessel with calomel, the calomel is completely converted into mercuric chloride, without separation of mercury.

Chloride of potassium, *chloride of sodium*, and especially *chloride of ammonium*, convert calomel into mercuric chloride, and unite with the latter forming double salts. Hence calomel should never be prescribed for internal use in conjunction with either of these alkaline chlorides, especially *sal-ammoniac*. [For further details relating to this and other reactions of calomel, see *Gmelin's Handbook*, vi. 48–53.]

Compounds of Mercurous Chloride.—*a.* With *Ammonia*. 100 pts. of dry calomel absorb 7.38 pts. ammonia-gas, forming the compound $\text{N}^2\text{H}^4(\text{Hg}^2)^2\text{Cl}^2$. The compound is black, but gives off ammonia on exposure to the air, and leaves white mercurous chloride (H. Rose). See MERCURY-HAKES, AMMONIACAL.

B. With *Chloride of Sulphur*. $\text{Hg}^2\text{Cl}^2.\text{SCl}^2$.—Produced by intimately triturating 27 pts. mercuric chloride and 6 pts. washed and dried flowers of sulphur, and gently heating the mixture in a porcelain dish covered with a glass funnel: it then effloresces in slender crystals. These must be taken out after cooling and the operation repeated as long as any efflorescence is produced. The compound may also be prepared by mixing calomel and dichloride of sulphur to a stiff paste in a retort, and gently heating the mixture after it has stood for twenty-four hours. The excess of sulphur-chloride then distils over first; afterwards the mass gradually melts and acquires a red colour; and finally the salt sublimes in right rectangular prisms with rhombic acumination: they are yellowish white when cold, and are instantly decomposed by water. (Capitaine, J. Pharm. xxv. 525 and 566.)

γ. With *Platinous oxide*.—This compound is produced in the form of a brown powder on mixing mercurous nitrate with platinic chloride. On heating it, mercurous chloride sublimes, and platinous oxide remains behind.

δ. With *Stannous Chloride*. $\text{Hg}^2\text{Cl}^2.\text{SnCl}^2$.—Prepared by intimately mixing 1 pt. of finely pulverised tin-amalgam (3 pts. tin to 1 pt. mercury) with 24 pts. calomel, filling a retort to about one-fourth with the mixture, and exposing it to a heat gradually rising to 250°. The mass when cold is pulverised and heated in a flask to 300°, whereupon the double chloride sublimes in very small white arborescent crystals, and metallic mercury remains. The crystals are decomposed by water. (Capitaine, J. Pharm. xxv. 549.)

e. With *Sulphuric anhydride*.—Calomel absorbs the vapour of sulphuric anhydride, forming a white translucent mass. (H. Rose, Pogg. Ann. xlv. 326.)

Mercuric Chloride. Hg^2Cl^2 .—*Protochloride*, *Bichloride*, *Muriate of Mercury*, *Corrosive Sublimate*, *etzender Quecksilber-sublimat*, *Aetzsublimat*, *Sublimat*; *Deutochlorure de Mercure*, *Sublimé corrosif*; *Mercurius sublimatus corrosivus*, *Hydrargyrum corrosivum album*.

This compound is produced:—1. By burning mercury in excess of chlorine gas.—2. By dissolving mercury in aqua regia containing excess of hydrochloric acid, evaporating, dissolving the residue in boiling water, and leaving the salt to crystallise by cooling.—3. By dissolving mercuric oxide in hydrochloric acid, and in general by double decomposition of mercuric oxide or a mercuric salt with metallic chlorides.

It is prepared on the large scale by decomposing mercuric sulphate with chloride of sodium. An intimate mixture of equal parts of common salt and mercuric sulphate (prepared by boiling 4 pts. mercury with 5 pts. strong sulphuric acid, till the mixture is reduced to a dry saline mass) is exposed to a gradually increasing heat, in a glass flask having a long wide neck, or better in a narrow-necked retort; mercuric chloride then sublimes on the cold part of the vessel, while sulphate of sodium remains behind. On account of the extremely poisonous nature of the vapours, the process must be performed under a chimney having a good draught. The mercuric sulphate frequently contains a small quantity of mercurous sulphate, which is converted by the chloride of sodium into calomel: to prevent this contamination, a small quantity of peroxide of manganese is added to the mixture; or 10 pts. mercury, 3 common salt, 3 peroxide of manganese, 11 sulphuric acid and 3 water, are triturated together, and the mixture is then heated as above:

Another very good method is to mix a boiling concentrated solution of mercurous nitrate with concentrated hydrochloric acid as long as a precipitate is formed, and boil the latter with a quantity of hydrochloric acid equal to that which was used for the precipitation. The reaction is:

The solution on cooling deposits the mercuric chloride in beautiful crystals.

Mercuric chloride crystallises in two forms, both belonging to the trimetric system. The crystals which separate from the alcoholic solution exhibit the combination ∞P , $\bar{\text{P}}\infty$, ∞P , $\bar{\text{P}}$. Ratio of axes $a : b : c = 0.7254 : 1 : 1.0686$. Angle $\infty\text{P} : \infty\text{P}$ in the macrodiagonal principal section = $71^\circ 55'$; $\bar{\text{P}}\infty : \bar{\text{P}}\infty$ in the basal principal section = $93^\circ 48'$. For the crystals obtained by sublimation, $a : b : c = 0.9347 : 1 : 0.3396$. Angle $\infty\text{P} : \infty\text{P}$ in the macrodiagonal principal section = $86^\circ 8'$; $\infty\bar{\text{P}}2 : \infty\bar{\text{P}}2 = 50^\circ 6'$; $\bar{\text{P}}\infty : \bar{\text{P}}\infty$ in the basal principal section = $37^\circ 30'$; $2\bar{\text{P}}\infty : 2\bar{\text{P}}\infty$ in the same $68^\circ 22'$. The crystals exhibit these faces together with $\infty\bar{\text{P}}\infty$. They are white, and exhibit various degrees of translucency up to complete transparency. Specific gravity = 5.4032 (Karsten); 5.420 (Boullay). Vapour-density 9.8 (Mitscherlich): by calculation, $9.48 \left(\frac{200 + 2 \cdot 35.5}{2} \times 0.0693 \right)$.

Mercuric chloride melts at 265° , boils at 296° , and volatilises somewhat more easily than calomel, even at ordinary temperatures. It has a disagreeable metallic taste and is a very powerful acid poison. It dissolves in water, alcohol and ether. According to Poggiale, 100 pts. water at different temperatures dissolve the following quantities of mercuric chloride.

Temperature. °	Quantity of salt dissolved.	Temperature. °	Quantity of salt dissolved.
5	5.73	60	13.86
10	6.67	70	17.29
20	7.39	80	24.32
30	8.43	90	37.05
40	9.62	100	58.96
50	11.34		

In alcohol the salt is much more soluble, requiring only $2\frac{1}{2}$ pts. at ordinary temperatures, and $1\frac{1}{2}$ pts. at the boiling point of alcohol; and it is almost equally soluble in ether. Hence when an aqueous solution of mercuric chloride is shaken up with ether, the ether extracts the greater part of it. Mercuric chloride volatilises in somewhat considerable quantity with the vapours, when its alcoholic or ethereal solution is boiled.

Mercuric chloride dissolves in considerable quantity in boiling concentrated hydrochloric acid, and the solution solidifies on cooling to a crystalline mass having a mother-of-pearl lustre, which, however, becomes fluid again at the heat of the hand. This mass consists, according to Boullay, of an acid mercuric or hydromercuric chloride $2\text{HgCl}_2 \cdot \text{HCl}$. When exposed to the air, it effloresces, gives off the excess of acid, and leaves the neutral chloride. Mercuric chloride likewise dissolves with great facility in nitric acid, and crystallises from the solution by cooling or evaporation. Sulphuric acid has no action upon it.

Many metals, viz. *arsenic, antimony, bismuth, zinc, tin, lead, iron, nickel, and copper*, decompose mercuric chloride in the dry way, withdrawing the half or the whole of its chlorine, and separating calomel or metallic mercury, which latter forms an amalgam with the excess of the other metal. *Arsenic* forms trichloride of arsenic and a brown sublimate. An intimate mixture of 3 pts. *antimony* and 1 pt. corrosive sublimate, well pressed into a glass, becomes hot and liquid in the course of half an hour, and on the application of heat, yields trichloride of antimony and metallic mercury. Tin heated with mercuric chloride yields a distillate of stannic chloride, and a grey residue containing calomel and stannous chloride. Many metals also reduce mercury from the aqueous or alcoholic solution of the chloride. Most metals throw down calomel together with the mercury; but *zinc, cadmium, and iron* precipitate nothing but mercury, zinc being thereby converted into a semi-fluid amalgam, and cadmium forming an amalgam which crystallises in beautiful needles. For the other reactions of mercuric chloride in solution, see p. 900.

Compounds of Mercuric Chloride. a. With *Ammonia*.—When mercuric chloride is gently heated in a stream of ammoniacal gas, the latter is absorbed, and the compound fuses by the heat evolved in the combination. The product was found by Rose to contain $\text{HgCl}_2 \cdot \text{NH}_3$. This compound boils at 590° , and may be distilled without loss of ammonia; it is decomposed by water. — (See MERCURY-BASES, AMMONIACAL.)

β. With other *chlorides*.—Mercuric chloride unites with many other metallic chlorides, forming crystallisable double salts. They are prepared, for the most part, by mixing the aqueous solutions of the two salts in the required proportions, and crystallising by spontaneous evaporation.

Ammonium-salts.—One of these double salts has long been known as *sal alembroth*. It crystallises in flattened rhombic prisms, $2\text{NH}_4\text{Cl} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$, and is isomorphous with the corresponding potassium-salt. When exposed to dry air, it gives off its water without change of form. Kane has also obtained $\text{NH}_4\text{Cl} \cdot \text{HgCl}_2$, and the same with $\frac{1}{2}$ at. water, $2(\text{NH}_4\text{Cl} \cdot \text{HgCl}_2) \cdot \text{H}_2\text{O}$, the first in a rhomboidal form, and the second in long silky needles. — According to J. Holmes (Chem. News, v. 351) a solution of 25 pts. mercuric chloride and 1 pt. sal-ammoniac in hydrochloric acid deposits crystals of the salt $2\text{NH}_4\text{Cl} \cdot 9\text{HgCl}_2$; and on mixing this solution with a very large excess of hydrochloric acid, or by dissolving in that acid a mixture of 3 pts. mercuric chloride and 1 pt. sal-ammoniac, the salt $2\text{NH}_4\text{Cl} \cdot 3\text{HgCl}_2 \cdot 4\text{H}_2\text{O}$ is obtained.

The *chlorides of barium and strontium* form well-crystallised compounds with mercuric chloride, viz. $\text{BaCl}_2 \cdot \text{HgCl}_2 \cdot 4\text{H}_2\text{O}$, and $\text{SrCl}_2 \cdot 2\text{HgCl}_2 \cdot 2\text{H}_2\text{O}$. *Chloride of calcium* combines in two proportions with mercuric chloride. When the latter is dissolved to saturation in chloride of calcium, tetrahedral crystals separate from the solution, which are tolerably persistent in the air, and contain $\text{CaCl}_2 \cdot 5\text{HgCl}_2 \cdot 8\text{H}_2\text{O}$. After the deposition of these crystals, the liquid yields, when evaporated by a gentle heat, a second crop of large prismatic crystals, $\text{CaCl}_2 \cdot 2\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$, which are very deliquescent.

The *chlorides of cobalt and copper* also form crystallisable double salts; chloride of lead does not appear to form a double salt with mercuric chloride.

The *iron-salt*, $\text{FeCl}_2 \cdot \text{HgCl}_2 \cdot 4\text{H}_2\text{O}$, and the *manganese-salt*, $\text{MnCl}_2 \cdot \text{HgCl}_2 \cdot 4\text{H}_2\text{O}$, are isomorphous and crystallise in rhombic prisms. An excess of mercuric chloride dissolves in the latter salt, and crystallises on cooling in large rhombic crystals.

Chloride of magnesium forms two double salts, with mercuric chloride, viz. $\text{MgCl}_2 \cdot 3\text{HgCl}_2 \cdot \text{H}_2\text{O}$, and $\text{MgCl}_2 \cdot \text{HgCl}_2 \cdot 6\text{H}_2\text{O}$, both deliquescent. *Chloride of nickel* gives two compounds, one of which crystallises in tetrahedrons, like the calcium-salt.

Potassium-salts.—When an aqueous solution of potassium-chloride is saturated at 30° with pulverised mercuric chloride, the liquid decanted, a quantity of potassium-chloride added equal to that already present, and the solution left to evaporate, the salt $2\text{KCl} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$ is deposited in large rhombic prisms. If the solution saturated at 30° be left to evaporate without further addition of chloride of potassium, another salt $\text{KCl} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$ is obtained in delicate asbestos-like crystals; and lastly, a solution of potassium-chloride heated to 60° and saturated with mercuric chloride, solidifies on cooling to a mass of slender needles having the composition $\text{KCl} \cdot 2\text{HgCl}_2 \cdot 2\text{H}_2\text{O}$.

The *sodium-salt* $\text{NaCl} \cdot \text{HgCl}_2 \cdot 2\text{H}_2\text{O}$ crystallises in six-sided prisms.

The *zinc-salt* has not been analysed. An aqueous solution of zinc-chloride containing excess of mercuric chloride deposits the latter, on evaporation, in large beautiful crystals, after which a double salt slowly separates in very deliquescent plates and needles. (Bunsdorff.)

Mercuric Chloride with Acid Chromate of Ammonium.—A solution of equal parts of these two salts yields, by concentration and cooling, large, shining, rose-coloured, six-sided prisms, of the salt $\text{HgCl}_2 \cdot [(\text{NH}_4)_2\text{CrO}_4 \cdot \text{CrO}_3] \cdot \text{H}_2\text{O}$ (Richmond and Abel, Chem. Soc. Qu. J. iii. 202). The salt was discovered by Darby (Mem. Chem. Soc. i. 24), who however assigned to it a different formula. According to Zepharovich

(Wien. Akad. Ber. xxxix. 17) the crystals are monoclinic and exhibit the faces $\infty P_{\infty} . + \frac{1}{2} P_{\infty} . - \frac{1}{2} P_{\infty} . [P_{\infty}] . \{\frac{1}{2} P_{\infty}\} . \infty P . [\infty P_2] . + P . + \frac{1}{2} P$. Ratio of axes $a : b : c = 0.5087 : 0.6462 : 1$. Angle of b and $c = 84^{\circ} 3'$; $\infty P : \infty P$ in the clinodiagonal principal section = $76^{\circ} 42'$; $\infty P : \infty P = 98^{\circ} 41'$; $\infty P : [P_{\infty} = 117^{\circ} 6'$; $\infty P : \{\frac{1}{2} P_{\infty}\} = 135^{\circ} 38'$. Cleavage parallel to ∞P and $-\frac{1}{2} P_{\infty}$.

The mother-liquor, from which this salt has separated, yields by further evaporation beautiful red needles of the salt, $HgCl_2 \cdot 3[(NH_4)^2CrO_4 \cdot CrO_3]$. (Richmond and Abel.)

Mercuric chloride also forms double salts with the neutral and acid chromates of potassium, viz. $2HgCl_2 \cdot K_2CrO_4$ and $HgCl_2 \cdot K_2CrO_4 \cdot CrO_3$. See CHROMATES (i. 938).

Mercuric Chloride with Basic Cupric Acetate. $\left. \begin{matrix} (C^2H^3O)^2 \\ Cu^2 \end{matrix} \right\} O_4 \cdot 2Hg^2Cl_2$. This com-

pound is produced, according to Wöhler, on mixing the solutions of mercuric chloride and neutral cupric acetate, saturated at ordinary temperatures, and leaving the mixture to itself for some time; it then separates in radiate hemispheric groups of crystals having a very fine deep blue colour. It is nearly insoluble in cold water, and is decomposed by boiling water.

Mercuric chloride also unites with *sulphide of ethyl*, forming the compound $(C^2H^5)_2S \cdot HgCl_2$, already described (ii. 545); and with *sulphide of methyl*, forming a similar compound.

MERCURY, CYANIDE OF. See CYANIDES (ii. 253).

MERCURY, DETECTION AND ESTIMATION OF. 1. *Reactions in the dry way.*—Most mercury compounds are decomposed by heat, and give off metallic mercury; but mercurous chloride and bromide and mercuric chloride and iodide sublime undecomposed. All mercury-compounds, when thoroughly dried, intimately mixed with dry carbonate of sodium, and heated before the blowpipe in a tube closed at one end, are decomposed and give off metallic mercury, which condenses in the cold part of the tube. Those mercury-compounds which are volatile without decomposition, the chlorides for example, may escape decomposition by carbonate of sodium. In this case the mixture must be slightly moistened with water, the water expelled by gentle heating over the lamp, and removed with blotting paper, the tube being held horizontally to prevent the water from running down to the heated part. When the moisture is all expelled, the blowpipe flame is applied as before. This is an easy and certain method of detecting mercury. When the quantity of mercury present is very small, the sublimate which forms on the cold part of the tube may look, to the unassisted eye, like arsenic or antimony; but examination with a lens will show that it consists of minute liquid globules.

2. Reactions in Solution.

a. *Of Mercurous salts.* Normal or neutral mercurous salts are white; the basic salts are frequently yellow. Most of them are soluble in water, reddish litmus, have a metallic taste, and do not act very violently on the animal body. All soluble mercurous salts are partially decomposed by water, a basic salt being precipitated and an acid salt left in solution; free acid redissolves the basic salt.

Sulphydic acid and sulphide of ammonium form with mercurous salts a black precipitate of mercurous sulphide Hg_2S , insoluble in sulphide of ammonium and in nitric acid, soluble in nitro-muriatic acid and in sulphide of potassium.

Hydrochloric acid and soluble chlorides form, even in very dilute solutions, a white precipitate of mercurous chloride, which is insoluble in dilute acids, and is blackened by potash or ammonia. Boiling nitric acid dissolves it; boiling hydrochloric acid decomposes it into mercuric chloride which dissolves, and metallic mercury, which remains as a grey powder.

Iodide of potassium forms a greenish-yellow precipitate of mercurous iodide (always, however, mixed with mercuric iodide) soluble in excess.

Cyanide of potassium separates metallic mercury, the mercurous cyanide Hg_2Cy_2 , formed in the first instance, being resolved into mercuric cyanide, $HgCy_2$, and mercury.

Ferrocyanide of potassium forms a white; ferricyanide of potassium, a reddish-brown precipitate.

Phosphate of sodium and oxalic acid form white precipitates; *chromate of potassium*, a red; *gallic acid*, a brownish-yellow precipitate.

Mercurous salts are reduced by metallic copper and zinc, by stannous chloride, ferrous sulphate, sulphurous acid, and phosphorous acid, metallic mercury being separated as a grey powder.

All mercurous salts are converted into mercuric salts by boiling with nitric acid.

2. Of Mercuric salts. Normal mercuric salts (containing 2 at. of an acid radicle to 1 at. Hg) are colourless; the basic salts are frequently yellow. They are violent acrid poisons, and have a disagreable metallic taste. The normal salts redden litmus. Most of them are soluble in water. They are partially decomposed by water, with separation of a basic salt requiring free acid to dissolve it. The chloride, however, dissolves in water without decomposition; hence a solution of mercuric chloride differs in some of its reactions from that of the nitrate and of other salts which are partially decomposed by water. From their aqueous solutions, the mercury is, for the most part, precipitated in the metallic state by the same substances as from mercurous salts; but the complete reduction of the mercury is often preceded by the formation of a mercurous salt: such for example is the action of *phosphorous acid*, *sulphurous acid*, *stannous chloride*, metallic *copper*, &c. *Formic acid* reduces mercuric to mercurous chloride, and no excess of the reagent carries the reduction further, unless the solution be heated nearly to boiling. *Gold* does not by itself reduce mercury from its salts; but if a drop of a mercuric solution be laid on a piece of gold, and a bar of zinc, tin, or iron be brought in contact with the moistened surface, an electrolytic action is set up, and the gold becomes amalgamated at the point of contact.

Sulphydric acid and *alkaline sulphides*, added in excess to mercuric salts, throw down a black precipitate of mercuric sulphide, soluble in strong nitric acid. If, however, the quantity of the reagent added is not sufficient for complete decomposition, a white precipitate is formed, consisting of a compound of mercuric sulphide with the original salt, and often coloured yellow or brown by excess of the sulphide; this reaction is quite peculiar to mercuric salts.

Hydrochloric acid forms no precipitate in solutions of mercuric salts.

Ammonia and *carbonate of ammonium* form white precipitates, generally consisting of a mercurammonium salt. The *fixed alkalis* throw down a yellow precipitate of mercuric oxide (not hydrated), insoluble in excess. If, however, the solution contains a large quantity of free acid, no precipitate is formed, or only a slight one after a considerable time.

Carbonate of potassium or *sodium* throws down red-brown mercuric carbonate; but if any ammoniacal salt is present in the solution, the fixed alkalis and their carbonates throw down the white precipitate above mentioned. *Acid carbonate of potassium* or *sodium* also gives a brown-red precipitate with mercuric nitrate or sulphate; but with the chloride, it forms a white precipitate which afterwards turns red. The *carbonates of barium*, *strontium*, and *calcium* precipitate mercuric oxide from the solutions of the sulphate and nitrate, but not from the chloride.

Phosphate of sodium throws down white mercuric phosphate from the sulphate and nitrate, but not from the chloride. *Chromate of potassium* forms a yellowish-red precipitate.

Cyanide of potassium gives with mercuric nitrate a white precipitate soluble in excess: it does not precipitate the chloride.

Ferrocyanide of potassium forms, in solutions not too dilute, a white precipitate which gradually turns blue, prussian blue being formed, while the filtrate contains cyanide of mercury. *Ferricyanide of potassium* gives a white precipitate with the nitrate, no precipitate with the chloride.

Tincture of galls forms an orange-yellow precipitate with all mercuric solutions except the chloride.

Iodide of potassium produces a scarlet precipitate of mercuric iodide, soluble in excess either of the mercuric salt or of iodide of potassium.

3. Quantitative Estimation.

Mercury is generally estimated in the metallic state; sometimes, however, as mercuric sulphide HgS , or as mercurous chloride Hg_2Cl_2 . To separate it from its compounds in the metallic state, it may be distilled with *quicklime* in a tube of hard glass sealed at one end. Into this tube is introduced, first a layer of carbonate of calcium, about an inch long; then the mixture of the substance with quicklime; lastly a layer of quicklime about two inches long, and a plug of asbestos to keep the lime in its place. The open end of the tube is next drawn out into a narrow neck, and bent at an obtuse angle. The tube is laid in a combustion-furnace, the same as that which is used for organic analysis, the neck being turned downwards and made to pass into a narrow-mouthed bottle containing water, so as to terminate just above the surface of the water. The tube is then gradually heated by laying pieces of red-hot charcoal round it, beginning at the part near the neck containing the pure quicklime. This portion having been brought to a full red heat, the heat is carefully extended towards the middle part, to decompose the compound and volatilise the mercury: any portion of the compound that may volatilise undecomposed will be decomposed in passing over the red-hot lime at the end. Lastly, the back part of the tube containing the carbon-

the is heated, so as to evolve carbonic anhydride and sweep out all the mercury vapour contained in the tube. The quantity of carbonic anhydride thus evolved may be increased by mixing the carbonate of calcium with acid carbonate of sodium. The mercury condenses under the water in the bottle, which must be kept cold. The water is poured off as completely as possible; the mercury transferred to a weighed porcelain crucible; the greater part of the water which still adheres to it removed by means of blotting-paper; the drying completed over sulphuric acid; and the mercury finally weighed.

Mercury may also be precipitated from its solutions in the metallic state by *stannous chloride* or by *phosphorous acid* at temperatures above 60° ; the solution then decanted; the mercury washed with water, and dried in the manner just described.

If the mercury is mixed with a considerable quantity of organic matter, as in cases of mercurial poisoning, the organic matter may be destroyed by treatment with nitromuriatic acid in a distillatory apparatus (i. 365), and the liquid subjected to the action of a voltaic current, the negative pole being composed of a plate of platinum or gold. The mercury then collects on this plate, and may be estimated by weighing the plate before and after the experiment.

The precipitation of mercury in the form of mercurous chloride is best effected by means of *hydrochloric acid* and *formate of potassium or sodium*. If the mercury is contained in an alloy, the alloy must be dissolved in nitromuriatic acid; if it is contained in solution in the form of mercuric nitrate, hydrochloric acid must be added, the solution, in either case, nearly neutralised with potash, the formate then added, and the whole exposed for some days to a temperature between 60° and 80° (at the boiling heat the mercury would be reduced to the metallic state). The mercurous chloride then precipitates, and must be collected on a weighed filter, washed, dried at a gentle heat, and weighed.

According to the latest experiments of H. Rose (Pogg. Ann. ex. 529), the best of all methods of estimating mercury is to precipitate it as calomel from the solution of mercuric chloride by *phosphorous acid*, either at ordinary temperatures or at a very gentle heat; if the temperature rises above 60° metallic mercury is precipitated.

Mercury is also frequently precipitated from its solutions, as a sulphide, by *sulphydic acid*. In that case, if the precipitate consists of the pure protosulphide, Hg_2S , as when it is thrown down from a solution of corrosive sublimate, the precipitate may be simply collected on a weighed filter, washed, dried over the water-bath, weighed, and the quantity of mercury thence determined. But if, as is generally the case, the precipitate also contains free sulphur, as when it is thrown down from a solution containing a ferric salt or a considerable excess of nitric acid; or if it be precipitated in conjunction with the sulphides of other metals, then the mercury must be separated from it by distillation with lime, as above described. Or again, the mixture of sulphides may be converted into chlorides by gentle heating in a stream of chlorine gas, the volatile chloride of mercury passed into water, and the mercury precipitated from the solution by stannous chloride.

The quantity of mercurous salt present in a solution may also be determined by precipitation with hydrochloric acid. The solution must, however, be very dilute, and be kept cool; it must also contain but a very small quantity of free nitric acid, as a larger quantity would convert the mercurous into mercuric chloride. To determine the proportions of mercurous and mercuric salt, when they exist together in solution, the mercurous salt is first precipitated with hydrochloric acid, and the remaining mercury by stannous chloride or sulphydic acid.

Volumetric methods. C. W. Hempel (Ann. Ch. Pharm. ex. 176) estimates mercury in the form of mercurous chloride, by means of a standard solution of iodine in iodide of potassium, which dissolves it in the form of potassium-mercuric iodide:

The quantity of iodine used is estimated by a graduated solution of hyposulphite of sodium (i. 265), and the quantity of mercury is thence calculated.

Another method given by Hempel (Ann. Ch. Pharm. cvii. 98) consists in agitating the mercurous chloride with dilute sulphuric acid and *permanganate of potassium* till it is dissolved, and estimating the quantity of permanganate used for the purpose by means of a standard solution of oxalic acid.

When the mercury is in solution as a mercuric salt, it is precipitated as calomel by ferrous sulphate, or by any of the other methods above given.

4. Separation of Mercury from other Metals.

Mercury may be separated from all other metals, except arsenic and antimony, by its superior volatility. When it exists in the form of an amalgam, the compound is simply heated, and the quantity of mercury determined by the loss of weight. If it

exists as an oxide, chloride, &c., combined with compounds of other metals, it may be separated by distillation with *quicklime*, as above described. Its separation from the alkali and earth-metals, and from uranium, manganese, nickel, cobalt, iron, zinc, and chromium, may also be effected by precipitation with *sulphydric acid*. From bismuth and cadmium it may be separated by reduction with *stannous chloride*; from copper, by mixing the solution with excess of *cyanide of potassium*, and passing *sulphydric acid* through the liquid, whereby the mercury is precipitated as sulphide, while the copper remains dissolved; from lead, by precipitating that metal with *sulphuric acid*, with addition of alcohol (H. Rose), the sulphuric acid being added in excess, as otherwise a basic sulphate of mercury may be precipitated at the same time. From arsenic, tin and antimony, mercury is separated by the solubility of the sulphides of those metals in sulphide of ammonium.

Field (Chem. Soc. J. xii. 32) separates mercury from antimony, by digesting the precipitated sulphides with moderately strong *hydrochloric acid*, which dissolves the sulphide of antimony and leaves the sulphide of mercury.

From silver, mercury, if in the form of a mercuric salt, is easily separated by *hydrochloric acid*, which precipitates the silver alone as chloride. If the mercury is in the form of a mercurous salt, the two metals are precipitated together as chlorides, and the separation is then easily effected by *ammonia*, which dissolves the chloride of silver, and blackens the mercurous chloride; or they may be separated by *nitromuriatic acid*, in the cold, which dissolves the chloride of mercury, leaving the chloride of silver undissolved.

When mercury, silver, and lead occur together in a solution, it is best to bring all the mercury to the state of mercuric salt by boiling with nitric acid: the silver may then be precipitated by *hydrochloric*, and the lead by *sulphuric acid*. Or the separation may be effected by *cyanide of potassium*, the solution being first nearly neutralised by an alkaline carbonate, and cyanide of potassium added in excess. The addition of nitric acid throws down the whole of the silver as cyanide, leaving the mercury in solution as cyanide, and the lead as nitrate, from which the lead may be precipitated by an alkaline carbonate.

For the analysis of a mixture of mercuric oxide, cinnabar, and red lead, Wöhler recommends the following process: The mixture is digested with *nitric acid*, which dissolves the mercury as mercuric oxide, and resolves the red lead into protoxide, which dissolves, and dioxide, which remains undissolved (p. 553), the cinnabar being also left undissolved. The lead is precipitated from the solution by dilute *sulphuric acid*, and then the mercury by *sulphydric acid* or *stannous chloride*. The residue is then treated on the filter with a mixture of warm nitric and oxalic acids, which dissolves out the dioxide of lead, and the residual cinnabar is washed, dried, and weighed.

The separation of mercury from gold in solution, may be effected by precipitating the gold in the metallic state by warming the solution with *oxalic acid* (ii. 928), and afterwards adding *hydrochloric acid* to redissolve the oxalate of mercury, precipitated at the same time. If the *hydrochloric acid* were added at an earlier stage of the process, it would greatly retard the precipitation of the gold. The mercury must of course be in the mercuric state.

5. Atomic weight of Mercury.

The atomic weight of this metal was for many years estimated, according to the experiments of Sefström, made in 1812 (Schw. J. xxii. 328), at 101.26 for Hg', or 202.52 for Hg". Turner, however, in 1835 (Ann. Ch. Pharm. xiii. 14), by the analysis of mercuric oxide and chloride, obtained lower numbers, viz. from 200 to 200.3, and his results have been confirmed by the experiments of Erdmann and Marchand in 1844 (*ibid.* lii. 216). These chemists decomposed carefully prepared and dried mercuric oxide by ignition in a stream of dry carbonic anhydride; absorbed the liberated oxygen (part of which would otherwise recombine with the mercury) by ignited charcoal and copper; and collected the mercury which distilled over, the escaping gases being finally freed from mercury by passing through a tube containing gold-leaf. In five experiments, in each of which from 44 to 118 grms. mercuric oxide, Hg'O, were decomposed, they found from 92.594 to 92.604 per cent. mercury; mean 92.597 per cent. Hence the value of Hg is between 200.06 and 200.33; mean 200.14. It is usual to take as the true atomic weight of mercury, Hg' = 100, or Hg" = 200.

The vapour-density of mercuric chloride, which, according to the observations of Mitscherlich, is 9.8, gives a condensation to 1 vol. for the formula HgCl₂, and of 2 vols. for HgCl (p. 897). This result affords an argument in favour of the larger atomic weight and the diatomicity of mercury in the mercuric compounds, and we shall presently see that this view is further corroborated by the constitution of the organic compounds of mercury.

MERCURY, ETHIDE OF. See MERCURY-RADICLES, ORGANIC.

MERCURY, FLUORIDES OF. Mercury forms two fluorides, corresponding in composition with the chlorides.

Mercurous Fluoride. $(\text{Hg}^2)\text{F}^2$. Berzelius obtained this compound as a sublimate, mixed with mercurous chloride, by heating the latter with fluoride of sodium. It has been further examined by Finkener (Pogg. Ann. ex. 142), who obtains it by adding recently precipitated calomel to a solution of silver-fluoride (prepared by digesting silver-carbonate with hydrofluoric acid); the whole of the silver is then gradually precipitated, and the liquid evaporated over the water-bath, yields small yellow crystals of mercurous fluoride. An easier mode of preparation is to add recently precipitated mercurous carbonate to hydrofluoric acid, which dissolves it completely at first, with evolution of carbonic anhydride, but on addition of a larger quantity deposits mercurous fluoride as a heavy, light yellow, crystalline powder. From a solution in excess of hydrofluoric acid it is deposited in indistinct (apparently cubic) crystals.

Mercurous fluoride is partly dissolved by water, partly decomposed into mercurous oxide and hydrofluoric acid. It is blackened even by moist air, especially if exposed to light. It is also decomposed when heated above 260° in dry air, mercury subliming, and the glass vessel becoming corroded. From the solution of the compound in hydrofluoric acid, *potash* throws down mercurous oxide; *ammonia*, a black precipitate containing metallic mercury and quickly turning grey, while the filtered liquid contains mercuric oxide and soon deposits a white mass containing mercury, ammonia, and fluorine. Dry mercurous fluoride is decomposed in like manner, by the prolonged action of aqueous *ammonia*, into metallic mercury and a mercuric compound. It slowly absorbs ammonia gas, turning black and being converted into fluoride of mercurous-ammonium $\text{N}^2\text{H}^6(\text{Hg}^2)\text{F}^2$.

Mercurous Silicofluoride, $\text{Si}^2(\text{Hg}^2)\text{F}^4.2\text{H}^2\text{O}$, is deposited from the solution of mercurous carbonate in hydrofluosilicic acid, in transparent, colourless, prismatic crystals. (Finkener.)

Mercuric Fluoride. Hg^2F^2 . Mercuric oxide added to hydrofluoric acid is converted into an orange-yellow powder, consisting of an oxyfluoride, and by repeatedly treating this compound with hydrofluoric acid, mercuric fluoride is deposited as a white crystalline mass containing $\text{HgF}^2.2\text{H}^2\text{O}$. The same product is obtained by adding dry mercuric oxide to a large excess of aqueous hydrofluoric acid (containing about 50 per cent. HF) (Finkener, Pogg. Ann. ex. 628). According to Frémy (Ann. Ch. Phys. [3] xlvii. 6), mercuric fluoride is obtained in long colourless hydrated needles (frequently, however, contaminated with hydromercuric fluoride or mercuric oxyfluoride) by slowly evaporating a solution of mercuric oxide in excess of hydrofluoric acid. Finkener, however, did not obtain crystals in this manner.

Hydrated mercuric fluoride decomposes at 50° , giving off hydrofluoric acid together with water, and leaving the oxyfluoride. It is permanent in dry air at ordinary temperatures, but is decomposed by water, yielding mercuric oxyfluoride and a solution of hydrofluoric acid containing a small quantity of mercuric oxide. A solution of mercuric fluoride in hydrofluoric acid mixed with a slight excess of ammonia, deposits, after some time in the cold, and immediately when heated, a white gelatinous precipitate, which, when washed and dried over sulphuric acid, consists of ammonio-mercuric oxyfluoride $2\text{NH}^4.\text{Hg}^2\text{F}^2\text{O}$. (Finkener.)

Mercuric Silicofluoride and Silico-oxyfluoride.—A solution of mercuric oxide in hydrofluosilicic acid yields by evaporation small pale yellow needles, which were regarded by Berzelius as mercuric silicofluoride; but according to Finkener they consist of a silico-oxyfluoride $\text{Hg}^2\text{Si}^2\text{F}^4.\text{Hg}^2\text{O}.3\text{H}^2\text{O}$. This compound is resolved by water, even at ordinary temperatures, into a soluble acid salt and an insoluble yellow pulverulent basic salt.

A solution of mercuric oxide in hydrofluosilicic acid, concentrated so far that oxy-silicofluoride begins to separate, and then left to itself at a temperature below 16° , yields colourless rhombohedral crystals grouped like steps, probably consisting of hydrated mercuric silicofluoride $\text{Hg}^2\text{Si}^2\text{F}^4.6\text{H}^2\text{O}$. They are very unstable and deliquesce when slightly heated, but effloresce over sulphuric acid. (Finkener.)

A double salt of mercuric fluoride with fluoride of ammonium is produced, according to Berzelius, by treating mercuric fluoride with aqueous ammonia.

MERCURY, IODIDES OF. Mercury unites with iodine in three or four proportions, forming a mercurous and mercuric iodide analogous to the chlorides, also a mercurous-mercuric iodide, and perhaps a periodide. The two elements unite directly, the combination, when large quantities are employed, being attended with considerable rise of temperature.

Mercurous Iodide. $(\text{Hg}^2)\text{I}^2$.—This compound is produced by triturating 200 pts. mercury with 127 pts. iodine or 454 pts. mercuric iodide, with addition of a Vol. III. 3 M

little alcohol, and removing any mercuric iodide that may be formed in the first instance, or remain unacted upon in the second, by solution in alcohol, which leaves the mercurous iodide undissolved. It may also be obtained by precipitating a mercurous salt with iodide of potassium. The acetate is best adapted to the purpose, yielding at once pure mercurous iodide. When the nitrate is used, the precipitate is frequently contaminated with mercuric iodide, either formed directly from mercuric nitrate in the solution, or by the oxidising action of free nitric acid in the solution on the precipitated mercurous iodide.

Mercurous iodide is a greenish-yellow powder of specific gravity 7.65 to 7.76. It is very sparingly soluble in *water*, quite insoluble in *alcohol*; *ammonia* dissolves it partially, leaving a grey residue. Mercurous iodide is very unstable, being easily resolved, under various circumstances, into metallic mercury and mercuric or mercurous-mercuric iodide. When heated, it yields a sublimate of metallic mercury and mercurous-mercuric iodide. When treated with *hydriodic acid* or with solutions of *iodide of potassium* or other metallic iodides, it is resolved into mercury and mercuric iodide, which unites with the other iodide, forming a soluble salt. In the moist state it is decomposed and blackened by exposure to *light*.

Mercurous iodide is used in medicine, and in preparing it for that purpose the greatest care must be taken to insure its perfect freedom from mercuric iodide, which is a violent poison. To test its freedom from this admixture, W. Squire (Jahresb. 1862, p. 217) heats it with *aniline*, whereupon, if it contains mercuric iodide, the well-known magenta colour is produced, whereas if the mercurous iodide is quite pure, no coloration takes place.

Mercurous-mercuric Iodide. $\text{Hg}^{\text{I}}_2 = (\text{Hg}^{\text{I}})^2\text{I}^2_2\text{Hg}^{\text{I}}_2$.—Prepared by precipitating mercurous nitrate with iodide of potassium, the precipitate not being collected till it has acquired a yellow colour. According to Boullay, it is best to mix the solution of potassium iodide with $\frac{1}{2}$ at. iodine, in which case mercurous-mercuric iodide is precipitated at once. The compound may also be obtained by triturating mercuric iodide with one-third as much mercury as it already contains ($3\text{HgI}_2 + \text{Hg} = \text{Hg}^{\text{I}}_2$).

Mercurous-mercuric iodide is a yellow powder which when heated turns red, melts, and may be sublimed without alteration. The sublimed crystals have a dark carmine-red colour while hot, but become yellow on cooling (Ingliš, Colin). The compound is insoluble in *water* and in *alcohol*, the latter not extracting any mercuric iodide from it. It remains unaltered when kept in the dark; but becomes dark coloured on exposure to *light*. *Hydriodic acid* and solutions of *iodides* first resolve it into mercurous and mercuric iodide, the latter uniting with the soluble iodide, and afterwards decompose the mercurous iodide itself, as above described, with separation of metallic mercury. (Boullay.)

Mercuric Iodide. $\text{Hg}^{\text{II}}\text{I}_2$.—This compound may be produced by triturating 1 at. mercury with 2 at. iodine (200 pts. mercury to 254 iodine), moistened with alcohol; according to Mohr, however, the combination of the two elements in this way is never complete, the product always containing a certain portion of free iodine which escapes during the drying over the water-bath, also some mercurous iodide which is resolved by sublimation into mercuric iodide and metallic mercury. Dublanc pours 1 kilogramme of alcohol on 100 grammes of mercury, and adds 124 grms. iodine in successive portions of 10 grms. each, stirring after each addition till the alcohol has become colourless. After the last 4 grms. of iodine have been added, the liquid becomes permanently coloured, in consequence of the complete conversion of the mercury into mercuric iodide; the product is washed with alcohol. Mercuric iodide is, however, best prepared by precipitating mercuric chloride with iodide of potassium, or iodide of iron: a. 8 pts. mercuric chloride and 10 pts. iodide of potassium are dissolved in separate portions of water, the solutions mixed, and the resulting precipitate collected and carefully washed. β . 2 at. iodine immersed in water are converted into ferrous iodide by addition of iron-turnings; the resulting solution is immediately mixed with a solution of 1 at. mercuric chloride (HgCl_2), and the precipitated mercuric iodide is quickly separated from the liquid, to prevent it from being contaminated with the basic ferric chloride which is gradually deposited from the solution.

Mercuric iodide thus obtained is a powder of a splendid scarlet colour, very slightly soluble in *water*, more soluble in *alcohol*, especially when hot, somewhat soluble also in *ether*. It dissolves easily in aqueous *iodide of potassium*, and crystallises from the solution in beautiful red quadratic octahedrons, also in the combinations $\text{P} \cdot \text{oP}$, $\infty\text{P} \cdot \text{oP}$, $\text{P} \cdot \text{P}$, and $\infty\text{P} \cdot \text{oP}$. Length of principal axis = 1.997. Angle $\text{P} : \text{P}$ in the terminal edges = $96^\circ 24'$; in the lateral edges $141^\circ 0'$. Cleavage perfect parallel to oP . Specific gravity = 6.2009 (Kursten); 6.320 (Boullay); 6.91 (Schiff).—The red iodide turns yellow when gently heated, melts at a higher temperature, and sublimes in bright yellow rhombic prisms exhibiting the combination

∞P . ∞P , and having the angle $\infty P : \infty P = 66^\circ$ (*Kopp's Krystallographie*, pp. 160, 257). Mercuric iodide is therefore dimorphous, and exhibits a red colour in one of its forms, a yellow colour in the other. The red modification is much more stable than the yellow; in fact the yellow crystals, even when left to themselves at ordinary temperatures, gradually recover their original colour and crystalline structure, being converted into an aggregate of the red crystals; the same change takes place instantly when the yellow crystals are pressed, rubbed, or scratched. The yellow iodide retains its colour longest when it has been prepared by subjecting the pulverised red iodide to a moderate heat. The yellow crystals obtained by sublimation often turn red on cooling, in consequence of the friction or agitation resulting from the contraction of the glass vessel, or of the crystals themselves (Mitscherlich). Mercuric iodide precipitated from the solution of the chloride by iodide of potassium, is likewise yellow at the first instant of precipitation, but quickly turns red, even while immersed in the liquid. In this case the course of the alteration may be easily watched under the microscope—yellow rhombic laminae being observed in the first instance, which continually diminish in bulk, becoming truncated on their edges and angles, and ultimately disappearing, while red quadratic octahedrons appear in their place (Warington). The solutions of mercuric iodide in alcohol ether, aqueous iodide of potassium, &c., are colourless, and may therefore be supposed to contain the yellow modification; if, however, the iodide separates slowly from them in crystals, these crystals are red; but if the separation takes place rapidly, as for example when the alcoholic solution is poured into water, the iodide is yellow at the first instant of separation, but very soon turns red. According to Reynoso (*Compt. rend.* xxxix. 696), an alcoholic solution of the iodide which has been kept for some time gives immediately a red precipitate with water. Schiff (*Ann. Ch. Pharm.* cxi. 371), on the other hand, found that an alcoholic solution which had been kept for fifteen months, still gave a yellow precipitate with water; and the yellow crystals which formed in it likewise remained unaltered in colour. Schiff also finds that the alcoholic solution, when mixed with water, first becomes quite milky, and after a few hours deposits shining yellow rhombic plates with angles of $114^\circ 30'$ and $65^\circ 30'$, and exhibiting beautiful coloured spectra under the polarising microscope.

Potassium triturated with mercuric iodide, abstracts the iodine with incandescence. A similar action is exerted by many of the heavy metals on trituration, either alone or with water, the resulting iodide sometimes uniting with the iodide of mercury to form a double salt; *zinc* and *tin* form amalgams with the liberated mercury. [For the behaviour of the individual metals, see *Gmelin's Handbook*, vi. 38.] When mercuric iodide is boiled with aqueous *potash*, mercuric oxide separates, and a yellow solution is formed containing a potassium-mercuric iodide, $2KI \cdot 3HgI^2$:

which, on cooling, first deposits mercuric oxide, and then greenish-yellow needles of $KI \cdot HgI^2$. Alcoholic potash acts in like manner and more easily. *Soda*, *baryta*, and *strontia* likewise act in a similar manner, producing double iodides; *lime*, *carbonate of potassium*, and *carbonate of sodium* do not decompose mercuric iodide when boiled with it in water; but if alcohol be substituted for the water, decomposition takes place, the alcohol appearing to favour the action by its solvent power. Mercuric iodide dissolves in aqueous *hypochlorite of calcium* when the solution is heated; and as it begins to boil, deposits periodate of calcium in the form of a white jelly, while mercuric chloride remains dissolved (Rammelsberg). When *chlorine gas* is passed into water in which mercuric iodide is suspended, a bright yellow solution is formed, containing mercuric chloride and trichloride of iodine. (Filhol.)

Double salts of Mercuric Iodide.—Mercuric iodide unites with the more positive metallic iodides, forming a series of double salts, *Bunsendorf's* iodo-hydrates, which have been particularly studied by Boullay (*Ann. Ch. Phys.* [2] xxxiv. 345). They are obtained, for the most part, by dissolving mercuric iodide in the solution of the positive iodide, and evaporating the solution. Mercuric iodide likewise forms double salts with metallic chlorides.

Ammonio-mercuric Iodide, $(NH^4)^2HgI^2 \cdot 3H^2O$, or $2NH^4 \cdot HgI^2 \cdot 3H^2O$, separates in yellow needles from a hot solution of mercuric iodide in iodide of ammonium, after pure mercuric iodide has been previously deposited. When heated, it melts and sublimes, partly unaltered, partly decomposed. Water separates mercuric iodide from it. (Boullay.)

Baryto-mercuric Iodide.—A solution of mercuric iodide in aqueous iodide of barium, after being freed from excess of mercuric iodide by cooling and dilution, deposits yellow crystals, soluble in water, which, according to Boullay, have probably the composition $Ba \cdot HgI^2$. A hot saturated solution of mercuric iodide in iodide of barium deposits, on cooling, a portion of the mercuric iodide, and the mother-liquid yields by

evaporation, crystals apparently consisting of $\text{BaHg}^2\text{I}^6 - \text{BaI}^2.2\text{HgI}^2$. The crystals decompose when dried at a high temperature, or when dissolved in a large quantity of water, mercuric iodide separating. (Boullay.)

Cadmio-mercuric Iodide is obtained by triturating cadmium filings with moist mercuric iodide, and exhausting with water. Crystallises in small, yellowish-white very soluble laminæ. (Berthémot.)

Calcio-mercuric Iodide. $\text{CaI}^2.2\text{HgI}^2$?—Obtained like the corresponding barium-salt, and decomposed in a similar manner by water.

Ferroso-mercuric Iodide.—The saturated solution of mercuric iodide in ferrous iodide yields, by evaporation over sulphuric acid, yellow-brown prisms, which quickly oxidise in contact with the air (v. Bonsdorff). A hot saturated solution of the two salts yields, after deposition of a portion of the mercuric iodide, brownish-yellow, very deliquescent needles, which are decomposed by water, and dissolved by strong acetic acid and by alcohol. (Berthémot.)

Magnésio-mercuric Iodide.—A hot saturated solution of mercuric iodide in iodide of magnesium, deposits mercuric iodide on cooling; and the remaining liquid yields greenish-yellow, needle-shaped crystals, which probably consist of $\text{MgI}^2.2\text{HgI}^2$, and are resolved by water into mercuric iodide, and a solution apparently containing $\text{MgI}^2.\text{HgI}^2$. (Boullay.)

Potassio-mercuric Iodide.—A concentrated solution of iodide of potassium takes up, at the boiling heat, 3 at. HgI^2 to 2 at. KI ; and of the 3 at. mercuric iodide, 1 at. is deposited on cooling, while the mother-liquor deposits the compound $2(\text{KI}.\text{HgI}^2).3\text{H}^2\text{O}$ in long yellow prisms. The crystals, when heated, first give off water, and then melt to a red liquid, from which mercuric iodide separates. They are soluble in alcohol and in ether, but water decomposes them, separating about half the mercuric iodide, and the liquid then yields by evaporation a saline mass, which may be regarded as $2\text{KI}.\text{HgI}^2$ (Boullay). Dilute acids decompose the crystals, separating the mercuric iodide. Potassio-mercuric iodide is likewise easily produced by boiling a solution of potassium-iodide with mercuric oxide.

Sodio-mercuric Iodide.—Iodide of sodium reacts with mercuric iodide in a similar manner to iodide of potassium. The solution, after depositing 1 at. mercuric iodide, yields by evaporation, a yellow, non-crystallising mass, which turns red when rubbed or scratched, from separation of mercuric iodide.

Strontio-mercuric Iodide, prepared like the corresponding barium-compound, forms yellowish needles.

Zinco-mercuric Iodide, prepared by Bonsdorff, crystallises in yellow, very deliquescent, rhombic prisms.

Periodide of Mercury, HgI^2 ? is obtained, according to Hunt, by precipitating aqueous mercuric chloride with a solution of potassium-iodide previously saturated with iodine. It forms a purple-red powder, which is resolved into mercuric iodide and free iodine by heating or by exposure to the air. Gmelin regards it as a mixture of mercuric iodide with iodine.

MERCURY, IODOCHLORIDE OF.— $\text{Hg}^2\text{I}^2\text{Cl}^4$.—This compound is produced on dissolving mercuric iodide in a hot solution of corrosive sublimate, and separates on cooling in white, jagged, fern-like laminæ (Liebig). According to Boullay, a hot saturated solution of mercuric iodide in corrosive sublimate yields on cooling a yellow powder, $\text{Hg}^2\text{I}^2\text{Cl}^4$; a less saturated solution yields, after the yellow powder, pale-yellow crystals, which, as well as the powder, soon turn red, from separation of mercuric iodide.

MERCURY, IODOSULPHIDE OF. See MERCURY, SULPHIODIDE OF (p. 915).

MERCURY, MERCAPTIDE OF. Syn. with Sulphethyrate of mercury. See ETHYL, SULPHYDRATE OF (ii. 548).

MERCURY, METHIDE OF. See MERCURY-RADICLES, ORGANIC (p. 921).

MERCURY, NITRIDE OF. Hg^2N^2 . See TRIMERCURAMINE, under MERCURY-BASES, AMMONIACAL (p. 917).

MERCURY, OXIDES OF. Mercury unites with oxygen in two proportions, forming the mercurous and mercuric oxides, analogous in composition to the chlorides.

Mercurous Oxide. Hg^2O . *Black oxide of mercury* (also called *dioxide* and *suboxide* of mercury). It is produced by treating mercurous chloride, or the solution of a mercurous salt, with excess of caustic alkali. To preserve it from decomposition, it must be washed and dried in the dark. Donovan suspends finely-divided calomel in water, treats it at once with excess of potash, and then washes and

dries the product. The mercurous oxide thus obtained yields but few globules of mercury on trituration; but if too little potash be added in the first instance, there is formed, according to Donovan, a mercurous oxychloride; and on further addition of potash, a mixture of mercurous oxide, mercuric oxide and metallic mercury. According to Guibourt (Ann. Ch. Phys. [2] i. 422), it is impossible to obtain this oxide pure, because, during washing, even in the dark, it is partly resolved into a mixture of mercuric oxide and metallic mercury. The product formed by triturating mercuric oxide with mercury is merely a mixture.

Mercurous oxide is a brown-black powder, destitute of taste and smell. The specific gravity of that obtained from calomel by the action of caustic potash is 8.9503 (Karsten), 10.69 (Herapath). It is very unstable, being resolved, even on exposure to diffused daylight, or by slight trituration in a mortar, into mercuric oxide and metallic mercury. At a red heat, it is resolved into mercury and oxygen-gas. With aqueous phosphorous acid, it yields mercury and phosphoric acid. By potassium and sodium, at about the melting points of those metals, it is decomposed, with vivid ignition and slight detonation, yielding metallic mercury and an alkali. It detonates when struck with phosphorus. It is slowly decomposed by phosphoretted hydrogen gas (Graham). When boiled with aqueous iodide of potassium, it yields, metallic mercury and potassio-mercuric iodide; if the mercurous oxide is in excess mercurous iodide is formed at the same time (Berthelot, J. Pharm. xiv. 189). A concentrated solution of sal-ammoniac decomposes it in a similar manner, ammonia being evolved, and mercury being separated, together with mercuric chloride (Pagenstecher, Repert. Pharm. xxvii. 27; L. Thompson, Phil. Mag. [3] x. 179). Carbonate of ammonium likewise decomposes mercurous oxide into mercuric oxide and metallic mercury.

Mercurous salts.—Mercurous oxide dissolves in acids, forming the mercurous salts, which may also be produced by dissolving mercury, under particular conditions, in certain oxidising acids, such as nitric or sulphuric acid; also in some cases by precipitation.

The normal mercurous salts have the composition $(\text{Hg}^2)^n \text{A}^{(n)}$, $(\text{Hg}^2)^n \text{A}^{(n)}$, $(\text{Hg}^2)^n (\text{A}^{(n)})^n$ &c., the symbol $\text{A}^{(n)}$ denoting an n -atomic acid or chlorous radicle, such as NO^3 , SO^4 , &c., e.g.,

These salts may also be regarded as compounds of mercurous oxide with anhydrides, or acid oxides, e.g. the nitrate, as $\text{Hg}^2\text{O} \cdot \text{N}^2\text{O}^5$.

There are also basic mercurous salts, which may be regarded either as compounds of the normal salts with mercurous oxide, or as oxy-salts, analogous to the oxychlorides &c.; or again as formed on the type of two or more molecules of water, in which more than half the hydrogen is replaced by mercury, e.g.,

For the properties and reactions of mercurous salts see p. 899.

Mercuric Oxide. HgO . Red oxide of mercury (also called *bioxide* and *deutoxide* of mercury). This oxide was known to the Arabians in the eighth century. Gaber and afterwards Raymond Lullius showed how to prepare it by igniting mercury-nitrate; and Boyle, towards the end of the seventeenth century, discovered that it may be prepared by heating mercury in contact with the air.

Preparation.—1. By keeping mercury for a month or longer at a boiling heat in a flask filled with air, and having a long loosely-fitting tube adapted to its mouth: the oxide thus obtained is called in pharmacy, *Mercurius precipitatus per se*.—2. By exposing mercuric or mercurous nitrate to a high and gradually increasing temperature in a crucible, or, better, in a glass vessel surrounded with sand, as long as nitrous acid is evolved. To save nitric acid, the nitrate, moistened with water, may be previously triturated with an equal weight of mercury, till the latter is completely deadened: this preparation is called *Mercurius precipitatus ruber*. Care must be taken not to raise the temperature too high. The oxide prepared by this process on the small scale is a dull powder; in commerce, it occurs in shining crystalline grains. According to Gay-Lussac, the small unpulverised crystals of mercurous nitrate yield the second form of the oxide, but the pulverised salt yields the first form. The more perfect crystallisation of the oxide prepared on the large scale is undoubtedly due to the slower rate at which the heat increases.—3. By precipitating a dissolved mercuric salt with excess of potash, and washing the precipitate.

Impurities and Adulterations.—1. *Basic mercuric nitrate*, when the salt has not been sufficiently heated. The oxide containing this salt gives off nitrous vapours when gently heated in a retort. It may be purified in this manner, or by boiling with potash-ley, or by washing with water.—2. *Nitre*. May be completely removed by boiling-water.

—3. *Minium*. Remains in the form of fused protoxide of lead, when the mercuric oxide is strongly heated in a glass tube, or in the form of peroxide of lead, when the mercuric oxide is dissolved in nitric acid.—4. *Brick dust*. Remains behind, when the oxide is ignited or dissolved in nitric acid.—5. *Cinnabar*. Remains, when the oxide is dissolved in hydrochloric acid.

Properties.—Pure mercuric oxide is generally crystallo-granular and scaly, shining and of a bright brick-red colour; by pulverisation it acquires an orange-yellow colour, lighter as the powder is finer. When prepared on the small scale, it is a dull, flocculent, earthy mass or powder, of a brownish brick-red colour. When obtained by precipitating a mercuric salt with an alkali, it forms a light orange-yellow powder. Specific gravity: 11·000 (Pol. Boullay), 11·074 (Herapath), 11·1909 (Karsten), 11·29 at 4° in vacuo (Royer and Dumas), 11·136 (Plyfair and Joule).—When heated, it becomes vermilion-red, and afterwards violet black, but recovers its original colour on cooling. It has a repulsive metallic taste, and is a violent acrid poison.

The precipitated yellow oxide is more readily decomposed by heat and by chlorine than the red oxide obtained by the first or second method. The difference is attributed by Pelouze (Compt. rend. xvi. 50) to the difference of aggregation of the two varieties, the precipitated oxide being amorphous and the calcined oxide crystalline; but Gay-Lussac (*ibid.* xvi. 309) has shown that the difference is mainly due to the more finely divided state of the precipitated oxide; chlorine acts less readily on the calcined oxide, because the smaller surface presented by the latter quickly becomes covered with mercuric chloride, which impedes the further action of the chlorine; but if the two varieties of the oxide are subjected to the action of chlorine under water, which dissolves the mercuric chloride as fast as it is formed, no difference in the rate of action on the two can be perceived. The yellow as well as the red oxide is anhydrous.

Mercuric oxide is not quite insoluble in water; according to Wallace (Chem. Gaz. 1853, p. 345) 1 pt. of it dissolves in 200,000 pts. of cold water after long standing, and in 125,000 pts. after boiling and cooling of the liquid. The solution has a strong metallic taste; turns violet juice green; becomes covered on exposure to the air with shining films of metallic mercury; is turned brown by sulphydric acid, and milky by ammonia. (Guibourt, Donovan.)

Decompositions.—Mercuric oxide gradually turns black when exposed to *sunshine*, being superficially decomposed into oxygen and metallic mercury, according to Guibourt, or, according to Donovan, into oxygen and mercurous oxide. At a *red heat*, it volatilises completely, being resolved into oxygen gas and vapour of mercury. Part of the mercurial vapour again takes up oxygen, and the oxide thus formed collects on the surface of the mercury which passes over, and diminishes its fluidity. With *phosphorus*, mercuric oxide detonates under the hammer. Boiled with phosphorus and water, it yields phosphide of mercury and aqueous phosphoric acid (Pelletier); at ordinary temperatures, the same mixture yields fluid mercury and phosphoric oxide, no phosphoric or phosphorous acid dissolving in the water (Braamcamp and Siqueira). A phosphate is likewise formed at the same time (Gmelin). Aqueous *phosphorous acid* forms mercury and aqueous phosphoric acid (Braamcamp and Siqueira). Mercuric oxide mixed with *sulphur*, and heated in a retort, produces a tremendous explosion (Proust). Concentrated *sulphurous acid* boiled with this oxide, immediately converts it into fluid mercury, with formation of sulphuric acid. At ordinary temperatures, smaller quantities of sulphurous acid produce a rise of temperature amounting to 7·5°, and form a *white* powder, consisting of mercurous sulphate, part of which dissolves in the liquid. An excess of sulphurous acid turns this powder grey, and reduces it very slowly, but completely, to metallic mercury. So long as this change remains incomplete, the liquid still retains mercury, but is not rendered turbid by addition of common salt; nevertheless, it gives a precipitate with sulphide of ammonium, and after long standing, or immediately on boiling, deposits metallic mercury in the form of a grey powder; the precipitation of the mercury is complete, provided the quantity of sulphurous acid is not too small (A. Vogel). *Potassium* or *sodium* heated to the melting point, decomposes mercuric oxide with vivid combustion and slight detonation, yielding metallic mercury and alkali. (Gay-Lussac and Thénard.) *Zinc* and *tin* filings, and pulverised *antimony* heated with mercuric oxide, likewise occasion fiery decomposition. Solution of *stannous chloride* poured upon mercuric oxide reduces it to the metallic state, and is itself converted into stannic chloride, part of which is precipitated in the form of a basic salt, the action being attended with a rise of temperature amounting to 60° (A. Vogel). *Hydrated ferrous oxide* converts mercuric into mercurous oxide; so likewise do ferrous salts (Duflos,

Schw. J. lxx. 115). Heated solution of *sugar* reduces mercuric to mercurous oxide (A. Vogel). *Chlorine gas* decomposes mercuric oxide at a red heat, the products being oxygen gas and mercuric chloride; at lower temperatures, hypochlorous acid and mercuric chloride are formed. The latter sometimes combines with the excess of oxide, forming mercuric oxychloride.

Combinations.—1. With Ammonia.—Thénard's *fulminating mercury*, see MANURE-BASES, AMMONIACAL, p. 918.

2. With Lime.—This compound is obtained, according to Berthollet, by boiling mercuric oxide with lime and water, separating the solution from the undissolved portion, and evaporating the liquid to the crystallising point. It then separates in yellow transparent crystals.

3. Mercuric Salts.—These salts are formed by dissolving mercuric oxide in acids; also by the action of oxidising acids aided by heat on metallic mercury; also with evolution of ammonia, on boiling various ammonium-salts with mercuric oxide. The normal salts may be represented by the formula $Hg''A_n$, or $(Hg'')^n(A^n)^1$, the symbol A^n denoting an n -atomic acid or chlorous radicle, e.g.:

The basic salts may be represented by formulæ similar to those of the basic mercurous salts, e.g.:

Normal mercuric salts are, for the most part, colourless; the basic salts yellow; they have a nauseous metallic taste, and are violent acrid poisons. They are decomposed by water, especially at the boiling heat, with separation, generally of a basic salt, but sometimes of mercuric oxide, as from the nitrate, the solution retaining sometimes an acid mercuric salt, sometimes a free acid. Hence H. Rose (Pogg. Ann. cxvii. 298), regards mercuric oxide as the weakest of all basic oxides, no other oxide being precipitated from the solutions of its salts by water. In the solution of mercuric chloride, water forms no precipitate, either of oxide or basic salt, the oxide being precipitated from this solution only by strong bases, since mercury, like the other noble metals, has a stronger affinity for chlorine than for oxygen. Conversely, mercuric oxide precipitates strong bases from the solutions of their chlorides, but not of their oxygen-salts. Those oxides which, when added to a solution of mercuric chloride, do not form a precipitate either of oxide or oxychloride, are thrown down by mercuric oxide from their solutions in hydrochloric acid; whereas those which precipitate mercuric oxide from the solution of the chloride, are not thrown down by that oxide from the solutions of their own chlorides. Thus the *alkaline earths* are not precipitated from their solutions in hydrochloric acid by mercuric oxide. From solution of *manganous chloride*, the manganese is completely precipitated after some time, as manganous oxide (manganous sulphate, on the other hand, is not decomposed). From solution of *chloride of lead*, mercuric oxide throws down oxide of lead; from *chloride of zinc*, the red-brown oxychloride (sulphate and acetate of zinc are not decomposed by it). From the *chlorides of nickel and cobalt* it precipitates the protoxides of those metals, the former completely, the latter for the most part (the sulphates are not decomposed). From *ferrous chloride*, ferrous oxide is precipitated, the mercuric oxide immediately turning black, but becoming red again after a while; the liquid contains mercuric chloride, if the quantity of mercuric oxide present is not sufficient to form an oxychloride; and the insoluble residue consists of mercurous chloride and a ferric oxychloride, produced by the reaction, $2Hg''O + 2Fe''Cl^2 = (Hg'')^2Cl^2 + (Fe^3)^1O^2Cl^1$. From *ferric chloride*, mercuric oxide in excess throws down all the iron as ferric oxide, forming an insoluble mercuric oxychloride (ammonio-ferric sulphate is not altered by it). From *cupric chloride* it throws down all the copper as cupric oxide; cupric sulphate is decomposed by it after a long time only, the mercuric oxide being converted at the same time into a solid lump of basic mercuric sulphate and basic cupric sulphate. (H. Rose.)

MERCURY, OXYBROMIDE OF. *Basic mercuric bromide.* $\text{Hg}^2\text{Br}^2\text{O}^2$ or $3\text{Hg}^2\text{O} \cdot \text{Hg}^2\text{Br}^2$.—This compound is obtained, according to Löwig, by boiling mercuric oxide and bromide together in water, or by boiling a solution of the bromide with a quantity of potash not sufficient to precipitate it completely. As thus prepared, it is a yellow crystalline powder, and crystallises from its aqueous solution in yellow needles. Rammelsberg obtained it, as a dark-brown powder, by precipitating mercuric bromide with carbonate of sodium.—Mercuric oxybromide is insoluble in cold, somewhat soluble in hot water, easily soluble in absolute alcohol (Löwig), insoluble in aqueous alcohol (Rammelsberg). It is resolved at a gentle heat into oxygen gas, a sublimate of mercury, mercurous and mercuric bromide, and a residue of mercuric oxide (Löwig). By boiling potash, it is converted, according to Löwig, into pure mercuric oxide; whereas, according to Rammelsberg, it remains unaltered. Nitric acid dissolves mercuric oxide from it, and leaves the bromide. (Rammelsberg.)

MERCURY, OXYCHLORIDE OF. Mercuric chloride and oxide unite in several proportions, and the compounds may be obtained in various ways: as by the action of mercuric oxide on a solution of the chloride; by incomplete precipitation of the latter solution with caustic alkalis or alkaline carbonates; and finally, by the action of chlorine on mercuric oxide. According to Millon, 1 at. mercuric chloride unites with 2, 3, or 4 at. mercuric oxide; but it is difficult to avoid obtaining mixtures of these several compounds. The usual mode of preparing them is to mix a solution of mercuric chloride saturated at 15° , with a solution of perfectly pure monopotassic carbonate (KHCO_3) saturated at the same temperature. A precipitate of pure oxychloride is then at once obtained; whereas if a neutral alkaline carbonate be used, the oxide is precipitated:

a. $\text{Hg}^2\text{Cl}^2\text{O}^2 = \text{Hg}^2\text{Cl}^2 \cdot 2\text{Hg}^2\text{O}$, is obtained by mixing 1 pt. of the solution of monopotassic carbonate with 6 to 10 pts. of the solution of mercuric chloride, stirring and immediately collecting the precipitate in a filter. It is a brick-red non-crystalline powder containing yellow mercuric oxide, which may be separated from it by potash. When 1 pt. of the solution of the acid potassium-salt is mixed with 3 or 4 pts. of the mercuric solution, the liquid being well stirred and then left to itself, a bright yellow precipitate is first formed, which gradually turns red, especially on agitation, afterwards acquires a tinge of purple-red, and ultimately of violet. It has exactly the same composition as the preceding. When 1 pt. of the potassic solution is mixed with 3 pts. of the mercuric solution, and the liquid is briskly stirred with a glass rod, black streaks begin to form on the side of the vessel; and if the contents are poured out, and a fresh mixture prepared, and briskly stirred, a dark precipitate is formed, the colour of which gradually passes into shining black. It has the same composition as the preceding; but when treated with potash, it yields red mercuric oxide.

b. $\text{Hg}^2\text{Cl}^2\text{O}^3 = \text{HgCl}^2 \cdot 3\text{Hg}^2\text{O}$. Obtained on mixing the solutions in equal volumes, and leaving the mixture at rest. The liquid then becomes filled after a while with shining, golden-yellow, crystalline scales, from which potash separates yellow mercuric oxide.

γ. $\text{Hg}^2\text{Cl}^2\text{O}^4 = \text{HgCl}^2 \cdot 4\text{Hg}^2\text{O}$.—When 4 to 6 pts. of the potassic solution are mixed with 1 pt. of the mercuric solution, no precipitate is formed at first; but, after a while, carbonic anhydride is given off, and a brown crystalline crust, having the composition above given, forms on the surface of the liquid. The same compound is gradually deposited from all the liquids filtered from the preceding oxychlorides, and is likewise obtained by imperfect precipitation of a warm solution of mercuric chloride. Potash separates the red oxide from it. All the other oxychlorides are converted into this compound when treated with boiling water, the liquid then depositing, on cooling, shining crystalline scales, also consisting of the same compound, but containing the yellow modification of the oxide. The same compound is obtained, according to Thaulow, when chlorine gas is passed into water in which mercuric oxide is suspended; the analysis of the compound thus produced does not, however, quite agree with the formula of the tetrabasic chloride. (*Handwörterbuch der Chemie*, vi. 772.)

When a solution of mercuric chloride is boiled with mercuric oxide, or triturated with it, and then left to itself for a considerable time, several oxychlorides appear to be formed. A solution of mercuric chloride boiled with the oxide deposits, on cooling, a mixture of the several oxychlorides; and on decanting the liquid, as soon as it has cooled to 60° , it yields small rhombic crystals of the compound $\text{Hg}^2\text{Cl}^2\text{O}$ or $2\text{HgCl}^2 \cdot \text{HgO}$, which may be freed from admixed mercuric chloride by absolute alcohol. (Roucher.)

According to Roucher's latest experiments (*Ann. Chim. Phys.* [3] xxvii. 353; *Jahresb.* 1849, p. 283), the composition of the oxychloride formed by the action of mercuric chloride on mercuric oxide, is different, according as the red or the yellow

modification of the oxide is used in its preparation, and likewise varies with the temperature and the nature of the solvent. At high temperatures, whether the red or yellow variety of the oxide be employed, and whether the chloride be used in the state of aqueous or of alcoholic solution, the products formed are invariably the same, viz. a black insoluble compound, $\text{HgCl}_2 \cdot 2\text{HgO}$, containing the red oxide, and a white, somewhat soluble substance, consisting of $2\text{HgCl}_2 \cdot \text{HgO}$. At ordinary temperatures, the yellow oxide always produces the yellow compound $\text{HgCl}_2 \cdot 3\text{HgO}$. The red oxide, digested in the cold with excess of corrosive sublimate, dissolved either in water or in alcohol, forms black $\text{HgCl}_2 \cdot 2\text{HgO}$; but when the oxide is in excess, and the chloride is used in the state of aqueous solution and frequently renewed, a more energetic action takes place, and the compound formed is $\text{HgCl}_2 \cdot 6\text{HgO} \cdot \text{H}_2\text{O}$; by operating in a similar manner, but using a somewhat larger quantity of the chloride solution at first, the anhydrous compound $\text{HgCl}_2 \cdot 6\text{HgO}$ is produced. Finally, the nature of the product is influenced by trituration: for, by triturating the red oxide in the cold with solution of corrosive sublimate renewed at short intervals, the product $\text{HgCl}_2 \cdot 4\text{HgO}$ is obtained.

All the mercuric oxychlorides yield, when heated, a sublimate of mercuric chloride, or are further decomposed into oxygen, mercurous and mercuric chlorides, and a residue of mercuric oxide.

MERCURY, OXYCYANIDE OF. See CYANIDES (ii. 265).

MERCURY, OXYFLUORIDE OF. See p. 903.

MERCURY, OXYGEN-SALTS OF. For the general characters of these salts, see pp. 899, 900; and for the special descriptions, see the several Acids.

MERCURY, OXY-IODIDE OF. *Basic mercuric iodide.* $\text{Hg}_2\text{I}_2\text{O}_2 = \text{HgI}_2 \cdot 3\text{HgO}$.—This compound is obtained by melting the oxide and iodide together in the required proportions, or by heating the iodide with dilute potash-ley. It is a yellowish-brown powder, mostly mixed with excess of oxide. [For its reactions with ammonia, see MERCURY-BASES, AMMONIACAL, p. 919.]

MERCURY, PHOSPHIDE OF. This compound is formed:—1. By heating finely-divided mercury with $1\frac{1}{2}$ pt. phosphorus (Pelletier); 2. By digesting 2 pts. of mercuric oxide with $1\frac{1}{2}$ phosphorus and 1 water, mercuric phosphate being formed at the same time (Pelletier); 3. By decomposing heated calomel with vapour of phosphorus (H. Davy); 4. By boiling aqueous mercuric chloride with phosphorus (Boullay); 5. In the decomposition of aqueous mercurous nitrate by phosphoretted hydrogen gas (Thomson); 6. When phosphoretted hydrogen gas is passed over dry, slightly-heated mercuric chloride, whereupon the phosphide of mercury sublimes. (H. Rose.)

Phosphide of mercury (1 and 2) is black; may be cut with a knife; gives off, when distilled, first the phosphorus, and afterwards the mercury; and, when exposed to the air, gradually loses its phosphorus by oxidation. That prepared by method (3) is brown (H. Davy), brown-red (Berzelius); according to Davy, it remains solid at the boiling point of mercury, and may be preserved unaltered. That prepared by (6) has the form of dark-brown flakes. The preparation (6) is an orange-yellow sublimate, which, when somewhat suddenly heated, is resolved into phosphorus and mercury. (H. Rose, Pogg. Ann. xxiv. 335.)

MERCURY, PHOSPHOCHLORIDES OF.—a. $\text{Hg}_2\text{P}_2\text{Cl}_2 \cdot 3\text{H}_2\text{O} = \text{Hg}_2\text{P}_2 \cdot 3\text{HCl} \cdot 3\text{H}_2\text{O}$.—Formed by passing phosphoretted hydrogen-gas through an aqueous or alcoholic solution of mercuric chloride. It is a yellow powder, which, when heated in a retort, yields a large quantity of hydrochloric acid-gas, 77.59 per cent. metallic mercury, and a residue of phosphoric acid. By boiling with water, it yields metallic mercury and a solution of hydrochloric and phosphorous acids free from mercury. *Caustic potash* decomposes it in a similar manner. Heated with dilute *nitric acid*, it eliminates nitric oxide, and is converted into 86.77 per cent. of calomel. (H. Rose, Pogg. Ann. xl. 75.)

b. $\text{Hg}_2\text{P}_2\text{Cl}_4 = 3\text{HgCl}_2 \cdot 2\text{PCl}_3$.—Obtained by direct combination of pentachloride of phosphorus with mercuric chloride. It forms easily-fusible needles, which volatilise at about 200° , and decompose when suddenly heated. (Baudrimont, Compt. rend. lv. 361.)

MERCURY, SELENIDE OF. *Mercuric Selenide*, Hg^{80}Se , may be produced artificially by direct union of its elements at a high temperature. As thus prepared, it forms a tin-white mass, which, when strongly heated, sublimes without previous fusion in grey metallic-shining laminae. It obstinately resists the action of the greater number of solvents, but is dissolved by *nitromuriatic acid*, as mercuric selenite. *Nitric acid* produces the same oxidation, but only after long-continued boiling.

Selenides of mercury occur at Zorge and at Tilkeroide in the Harz, and near Clausthal. Their composition is exhibited in the following table:

	Tilkeroide. Schulz.	Zorge. Marx.	Clausthal. Kerl	
Mercury . .	74.02	74.5	75.11	74.82
Selenium . .	23.61	25.5	24.39	24.90
Sulphur . .	0.70			
	98.33	100.0	99.50	99.72

The Tilkeroide mineral contains also a trace of copper. When it is heated before the blowpipe, the greater part volatilises, leaving 11.85 per cent. of foreign matter, including 10.85 per cent. ferric oxide). The preceding analysis applies to the volatile portion. If the loss be reckoned as selenium, the mineral has very nearly the composition Hg^2Se . The analyses of the minerals from Zorge and Clausthal lead nearly to the

formula Hg^2Se , which is that of a mercurous-mercuric selenide containing $\text{Hg}^2\text{Se} \cdot 4\text{Hg}^2\text{Se}$. It is possible however that these minerals may really consist also of mercuric selenide Hg^2Se (Rammelsberg's *Mineralchemie*, pp. 35, 1010).

The native selenides of mercury are massive minerals, with compact granular texture and no cleavage. Hardness = 2.5. Specific gravity = 7.1 to 7.37 (of the Clausthal ore). Lustre metallic. Streak shining. Colour steel to blackish lead-grey.

Selenide of Mercury and Lead forms the mineral *Lehrbuchite*, occurring at Tilkeroide (pp. 558, 570).

Selenide of Mercury, Lead, and Copper.—Minerals having this composition occur at Tilkeroide and at Zorge in the Harz; they are intimate mixtures, in which a white or grey mineral crystallised in small cubes, and a violet mineral, may be distinguished. Two specimens analysed in Rammelsberg's laboratory gave

	Se.	Pb.	Cu.	Hg.	
a. (Specific gravity 5.74)	38.53	25.36	22.13	13.12	= 99.14
b. (" " 4.86)	34.19	43.05	17.49	3.61	= 98.34

MERCURY, SELENIO-SULPHIDE OF. *Onofrite*.—A mineral occurring with other ores of mercury near San Onofre in Mexico. It contains according to H. Rose's analysis (Pogg. Ann. xlv. 315), 6.49 per cent. selenium, 10.30 sulphur, and 81.33 mercury; whence it appears to be a compound, or perhaps an isomorphous mixture, of 1 at. HgSe and 4 at. HgS . In its physical characters it resembles mercuric selenide.

Del Rio (Pogg. Ann. xiv. 182) mentioned a grey mineral from Calabrias in Mexico containing 49 per cent. selenium, 1.5 sulphur, 24 zinc, and 19 mercury; also a red mineral likewise containing selenium, mercury, and zinc. Subsequently (*ibid.* xxxix. 526), he described the latter as a mixture of selenio-sulphide of mercury, selenide of cadmium, selenide of iron, and free selenium.

MERCURY, SULPHIDES OF. Mercury forms two sulphides, analogous to the oxides.

Mercurous Sulphide. Hg_2S .—This is the black precipitate formed by sulphydric acid or sulphide of ammonium in solutions of mercurous salts. It may be prepared by passing sulphydric acid gas through a solution of mercurous acetate; if the nitrate is used, the liberated nitric acid exerts an oxidising action on the precipitate. The best mode of preparation, according to Berzelius, is to drop a dilute solution of mercurous nitrate into a dilute solution of sulphhydrate of ammonium or potassium; or a solution of either of these sulphhydrates may be poured upon calomel recently precipitated and still moist.

Mercurous sulphide in the dry state is a deep-black powder; it is resolved at a gentle heat into mercuric sulphide and metallic mercury, which remains mixed with the sulphide in the form of small globules. At a strong heat, it yields a sublimate, first of metallic mercury, afterwards of cinnabar.

Mercuric Sulphide. HgS . This compound exists both amorphous and crystallised; in the former state it is black; in the latter, it has a fine red colour and constitutes the well-known pigment called cinnabar or vermillion.

a. *Amorphous Mercuric Sulphide*.—When mercury and sulphur are triturated together for a long time in the proportion 100 mercury to 16 sulphur, they unite and form black mercuric sulphide; the product thus obtained is called in pharmacy, *Aethiops mineralis*.—The same compound is formed by heating 6 pts. mercury with 1 pt. sulphur; but the product thus obtained is of rather uncertain composition, owing to the volatilisation of a portion of the sulphur; moreover it contains a considerable quantity of cinnabar, which remains undissolved on boiling with potash, whereas good *Aethiops* is wholly or almost wholly soluble in that liquid.—The amorphous sulphide

is also produced by precipitating the solution of a mercuric salt with excess of sulphuric acid or a soluble sulphide; by agitating mercury with pentasulphide of ammonium or potassium; and by exposing cinnabar to a very gentle heat in a close vessel.

Amorphous mercuric sulphide is a velvet-black powder or a greyish-black mass. When heated somewhat strongly in a close vessel, it yields a sublimate of cinnabar; but on heating it in contact with the air, the sulphur burns and the mercury volatilises; when ignited with caustic alkalis or alkaline carbonates, it gives off all its mercury and leaves a residue of alkaline sulphide (liver of sulphur). It withstands the action of most solvents, but is decomposed, with separation of sulphur, by very strong nitric acid; dilute nitric acid has scarcely any action upon it; nitromuriatic acid dissolves it with tolerable facility. It is likewise soluble in aqueous sulphide of potassium, and the solution solidifies on evaporation to a mass of slender colourless needles consisting of potassio-mercuric sulphide, $K^2HgS^2.5H^2O$, which is decomposed by water, with separation of black mercuric sulphide.

B. Crystallised mercuric sulphide. Cinnabar, Vermillion. Cinnabar occurs native, being in fact the most important ore of mercury: its principal localities have been already enumerated (p. 883). By far the greater part of the vermilion occurring in commerce is however prepared by sublimation of the amorphous sulphide.

Formation and preparation.—1. *In the dry way.*—Mercury, mercuric oxide, or trimercuric sulphate, sublimed with sulphur, yields cinnabar. When 5 or 6 parts of mercury are added to 1 part of melting sulphur, and the mixture is heated, with constant stirring, till the sulphur becomes thick, combination takes place suddenly, attended with evolution of light and heat, and with violent crackling and projection of the mass. The resulting compound exhibits a blackish-red colour, and frequently a distinct red streak; it may be regarded as cinnabar partly mixed with black sulphide of mercury, and partly with uncombined mercury and sulphur in a state of minute division. Now, when this crude product, after being pounded, is mixed with a small quantity of sulphur, and a glass flask half filled with it is loosely closed with a charcoal stopper, sunk to two-thirds of its depth in sand, and exposed for some hours to a red heat in a slow-drawing wind-furnace, a sublimate of pure cinnabar is obtained. The excess of sulphur, being more volatile than the cinnabar, escapes; foreign metals remain in the form of sulphides at the bottom of the flask. If the upper part of the flask becomes too hot, a portion of the cinnabar may be lost by volatilisation.

Old method of preparation in Amsterdam.—170 pounds of mercury are gradually added to 50 pounds of melted sulphur contained in a cast-iron pot, the materials being stirred up with an iron spatula, but not so rapidly as to give rise to active combustion—the mixture is poured out upon an iron plate, and broken into pieces after cooling—and the fragments are put into hand-jars capable of holding 1½ pounds of water. The subliming vessels are earthen cylinders 4 feet high, glazed within, and closed at the bottom; they are sunk to two-thirds of their depth in a furnace in which their lower part is heated to redness. A few hand-jars full of the mixture are thrown into each of these subliming vessels, and the contents left to crackle and burn till the greater part of the excess of sulphur volatilises, and the flame diminishes. The smooth, level opening is then covered with a thick, smooth plate of cast-iron; the plate removed as soon as a sufficient quantity of cinnabar has collected upon it; the cinnabar which has collected on the upper part of the vessel is pushed down again; a fresh plate put on, &c. &c. The contents of the cylinder are stirred up from time to time, and fresh material is introduced. The cinnabar, after being detached from the plates, is ground as finely as possible with rain-water.

Method of preparation in Idria.—A number of casks, each containing 8 pounds of ground sulphur and 42 pounds of mercury, are made to turn upon their axes for two or three hours, till the contents are converted, with slight evolution of heat, into a brown powder. 100 pounds of this powder are then introduced into an upright cast-iron cylinder, previously heated in a furnace; the cylinder is covered with an iron capital, kept down by weights till the crackling of the mass is over; and the iron capital is then replaced by one of stone-ware, having its beak connected with a tube and receiver, and the fire is increased. The best cinnabar collects in the capital, which is afterwards broken in pieces; that which condenses in the tube and receiver, if mixed with excess of sulphur, is added to the quantity introduced at the next sublimation. The cinnabar, after being finely ground with water, is well boiled with potash-ley, and washed with boiling and with cold water. (Mitscherlich, *Lehrbuch*.)

Chinese method.—1 part of sulphur and 4 parts of mercury are sublimed in an earthen vessel, to which an iron cover, kept constantly moist, is luted; the fire is kept up for four-and-twenty hours; the vessel broken up after cooling; the less pure sublimate separated; the purer portion pounded up; the powder sifted into a large vessel filled with water; the water, with the scum floating on it, is poured off after a while,

the process being twice repeated; and lastly, the sediment at the bottom is dried. (*N. Edinb. J. of Sc.* ii. 352.)

European cinnabar, whether prepared in the dry or in the wet way, always has a tinge of yellow; the Chinese, which is six times as dear, inclines to carmine colour, although no foreign matter can be detected in it, excepting a little glue. By the sublimation of common cinnabar with 1 per cent. of sulphide of antimony, a dark steel-grey cinnabar is obtained, which becomes brown-red when pulverised: but if it be finely ground, and repeatedly boiled with solution of liver of sulphur, then thoroughly washed and digested with hydrochloric acid, and afterwards washed and dried, it becomes exactly like the Chinese vermilion, but of a still finer colour. No antimony can be detected in it. (*Wehrle, Zeitschr. phys. v. Wiss.* ii. 27.)

The principal point to be attended to in the preparation of cinnabar by sublimation, is that no black amorphous sulphide shall get mixed with it.

2. *In the wet way.*—The black, amorphous sulphide of mercury obtained by the action of sulphydric acid, or of alkaline sulphhydrates or persulphides on mercury, its oxides, and salts, is converted by contact with alkaline persulphides, slowly in the cold, but quickly when heated, into the red sulphide.

Very fine cinnabar may be obtained by immersing recently precipitated "white precipitate" (p. 916) in a solution of sulphhydrate of ammonium, or in monosulphide of ammonium previously saturated with sulphur: the black colour which the precipitate first acquires passes, at a temperature between 40° and 50°, through red-brown into the beautiful deep red of Chinese vermilion, the change taking place more quickly as the liquid is more concentrated. The colour may be rendered still brighter by subsequent digestion with potash at a gentle heat. (*Liebig, Ann. Ch. Pharm.* v. 289; vii. 49.)

Brunner (*Pogg. Ann.* xv. 593) carefully triturates 100 pts. of mercury with 38 pts. of flowers of sulphur, till the whole is converted into black amorphous sulphide—a process which requires three hours for small quantities, and twelve hours if the quantity amounts to a few pounds—and heats it in a porcelain basin or a cast-iron pot, with a solution of 25 pts. of potassium-hydrate in 133 to 150 pts. of water, keeping the temperature uniformly at 45°, and never letting it rise above 50°. At first the mixture is continually stirred with the pestle, afterwards from time to time. The water which evaporates is replaced, so as not to allow the mixture to acquire the thickness of a jelly. When the reddening has once begun, which generally takes place in about eight hours, the heat must not be allowed to rise above 45°; and as soon as the red has attained its greatest degree of brightness, the vessel is removed from the fire, or else, which is better, the mixture is kept for some hours exposed to a gentler heat. It is then washed, and the mercury which remains metallic is separated by levigation, whereupon it yields from 109 to 110 per cent. of cinnabar, but little inferior to the finest native variety, and far superior to that obtained by sublimation. The above-mentioned proportion of the ingredients gives the largest amount of cinnabar; 100 pts. of mercury yield with 40 pts. of sulphur and 40 of potassium-hydrate, 107 cinnabar; with 28·3 sulphur and 51 potassium-hydrate, 94·2; with 33 to 40 sulphur and 60 potassium-hydrate, 81·5; and with 30 sulphur and 60 potassium-hydrate, only 47·3 cinnabar. (Brunner.)

Döbereiner (*Schw. J.* lxi. 380) gently heats mercury with a solution of pentasulphide of potassium, triturating it continually, till the mercury is converted into a dark red powder, a change which generally takes place in about an hour and a half; he then decants the liquid (which contains protosulphide of potassium, and by digestion with sulphur may be rendered fit for another preparation of cinnabar), and triturates the powder with a small quantity of dilute potash-ley at 40° or 45°, till it acquires a fiery red colour.

If the cinnabar has become brown from being heated too long with sulphur and potash-ley, it may be restored to the state of the finest vermilion by the addition of water and the application of a moderate heat. (*Storch, Repert. Pharm.* xxxv. 107.)

Th. Martius (*Kastn. Arch.* x. 497) places the ingredients in bottles closed with corks and packs them into a box, which is fastened to the upper beam of a saw-mill. In 24 or 36 hours, at ordinary temperatures, the most beautiful cinnabar is obtained; it is afterwards washed and dried. This method not only has the advantage of dispensing with the labour of trituration, but likewise prevents the hitherto unexplained passage of the cinnabar into the brown state, which is so liable to take place on the application of heat.

Adulterations.—*Brickdust* remains behind on ignition.—*Oxide of iron*, the same; it may also be dissolved out by hydrochloric acid.—*Red lead* remains behind on ignition in the form of a fused protoxide, and yields chloride of lead, with evolution of chlorine, on boiling the substance with hydrochloric acid; the chloride thus formed may be extracted by boiling water.—*Dragon's Blood*: Empyreumatic odour on the application of heat; gives a red colour to alcohol.

Properties.—Native cinnabar and many of the artificial varieties form hemihedral crystals belonging to the hexagonal system, the primary form being an acute rhombohedron, in which the length of the principal axis is 2.29, and R : R in the terminal edges 71° 48'. The most ordinary combination is R. oR, somewhat like *fig. 361* (ii. 224); also with ∞R , the latter sometimes predominating. Cleavage parallel to ∞R . Cinnabar obtained by sublimation assumes the form of fibrous masses. Specific gravity of the native mineral, 8.0 to 8.1; of a cleavable variety from Neumarktel, 8.998; of the artificially sublimed compound, 8.0602 (Karsten), 8.124 (Pol. Boullay). Hardness of the native mineral = 2 to 2.5. It is sectile and has a subconchoidal uneven fracture. In the mass it is cochineal coloured, transparent, and has an adamantine lustre; its powder is scarlet. It becomes brownish when gently heated; quite brown at 250°, and black at a higher temperature; but if the heat has not been strong enough to cause it to volatilise, it recovers its fine scarlet colour on cooling.

Pure mercuric sulphide contains 86.2 per cent. mercury and 13.2 sulphur; native cinnabar is, for the most part, nearly pure, the percentage of mercury varying from about 78 to 86 per cent.

In its chemical relations cinnabar, both natural and artificial, resembles the amorphous sulphide, excepting that it is still less easily attacked by solvents. Heated with iron, tin, antimony, and several other metals, it yields metallic mercury and a sulphide of the other metal. Caustic alkalis and alkaline carbonates also liberate the mercury at a red heat, while a mixture of metallic sulphide and sulphate remains behind; thus with lime:

Heated with protoxide of lead, it gives off sulphurous anhydride and mercury, leaving very pure metallic lead, and a fused slag, which, if the oxide of lead is not in very great excess, contains undecomposed cinnabar.

MERCURY, SULPHOBROMIDE OF. $\text{Hg}^2\text{Br}^2\text{S}^2$, $\text{Hg}^2\text{Br}^2.2\text{HgS}$. When sulphydric acid gas is passed through a solution of mercuric bromide, a white precipitate is at first formed, consisting of this compound, which is afterwards transformed by excess of sulphydric acid into black mercuric sulphide. The sulphobromide is also produced by digesting the black sulphide with the aqueous solution of the bromide. It is yellowish-white when dry; splits up into mercuric bromide and cinnabar when heated; is blackened by alkalis, but less quickly than the corresponding chlorine-compound. It is neither decomposed nor dissolved by nitric or sulphuric acid at the boiling heat.

MERCURY, SULPHOCHLORIDE OF. $\text{Hg}^2\text{Cl}^2\text{S}^2$. Produced by reactions similar to those above described for the sulphobromide, which it resembles in its properties and in most of its reactions. Heated in a current of chlorine gas, it yields chloride of sulphur and mercuric chloride.

MERCURY, SULPHO-IODIDE OF. $\text{Hg}^2\text{I}^2\text{S}^2 = \text{Hg}^2\text{I}^2.\text{Hg}^2\text{S}$. Produced like the preceding compound, which it resembles.

MERCURY-BASES, AMMONIACAL. (C. G. Mitscherlich, *Pogg. Ann.* ix. 387; xvi. 41.—Kane, *Ann. Ch. Phys.* [2] lxxii. 215.—Plantamour, *Ann. Ch. Pharm.* xl. 115.—Rammelsberg, *Pogg. Ann.* lv. 248.—Millon, *Ann. Ch. Phys.* [3] xviii. 333.—Hirzel, *Ueber die Einwirkung des Quicksilberoxyds auf das Ammoniak und die Ammoniak-verbindungen*, Leipzig, 1852; *abstr.* *Ann. Ch. Pharm.* lxxxiv. 258.—Schmieder, *J. pr. Chem.* lxxv. 129; *Jahresb.* 1858, p. 204.)—By the action of ammonia and its salts on mercury-compounds, a variety of substances are formed, some of which were originally regarded as compounds of ammonia with mercury-salts; e.g., ammonio-mercuric chloride $\text{NH}^2.\text{Hg}^2\text{Cl}^2$; ammonio-mercurous chloride, $2\text{NH}^2.(\text{Hg}^+)^2\text{Cl}^2$; ammonio-mercuric iodide, $2\text{NH}^2.\text{Hg}^2\text{I}^2$, &c. Kane, in accordance with his amidogen theory, regarded these compounds as containing amide of mercury, NH^2Hg , combined with other mercury- or amidogen-compounds. Hirzel and others have represented them as containing nitride of mercury, $\text{N}^2(\text{Hg})^2$, as a proximate constituent. Gerhardt first suggested that they contain ammonia-molecules, in which the hydrogen is more or less replaced by mercury; and this view has been further developed, in accordance with the ammonium-theory, these compounds being supposed to contain ammonium-molecules in which the hydrogen is wholly or partly replaced by mercury in the proportion of 100 or 200 pts. mercury to 1 pt. hydrogen, according as the compound is formed from a mercuric or a mercurous salt, thus:

Mercurammonium	$\text{N}^2\text{H}^2\text{Hg}^2$
Mercurosammonium	$\text{N}^2\text{H}^2(\text{Hg}^+)^2$
Dimercurammonium	$\text{N}^2\text{H}^2\text{Hg}^2$

Dimercurosammonium	$N^2H^4(Hg^2)^2$
Trimercurammonium	$N^2H^2Hg^2$
Trimercurosammonium	$N^2H^2(Hg^2)^2$
Tetramercurammonium	N^2Hg^4

None of the mercurammoniums have been obtained in the free state; but trimercuramine, Hg^2N^2 , is produced by the action of ammonia-gas on dry mercuric oxide.

Mercurammonium. $\frac{Hg''}{H^2}\{N^2$.—The *bromide* of this base, $\frac{Hg''}{H^2}\{N^2Br^2$, (like ϵ or η ,* p. 921) is produced by melting mercuric bromide at a gentle heat in ammonia gas, the salt then taking up about 3.4 per cent. of the gas. Water extracts bromide of ammonium from the product, and leaves a yellow powder which gives off ammonia when treated with aqueous sulphide of potassium, but not with caustic potash.

Bromide of Mercury and Mercurammonium. $N^2H^2.2Hg^2Br^2 = \frac{Hg''}{H^2}\{N^2Br^2$. $HgBr^2$, or *Bromide of Hydrogen and Dimercurammonium* $NH^2.Hg^2Br^2 = \frac{Hg''}{H^2}\{NBr^2$. HBr , (β), is produced by saturating mercuric bromide with ammonia gas. It is a white powder insoluble in water and in alcohol, sparingly soluble in ammonia, and is resolved by heat into nitrogen, ammonia gas, aqueous vapour, [γ hydrogen], and a sublimate of mercuric bromide.

Chloride of Mercurammonium.— $2NH^2.Hg^2Cl^2 = \frac{Hg''}{H^2}\{N^2Cl^2$, (ϵ). *Fusible white precipitate.* Obtained by precipitating a solution of ammonio-mercuric chloride (*alembroth salt*, p. 808) with potash (Wöhler), or by dropping a solution of mercuric chloride into a boiling solution of sal-ammoniac mixed with free ammonia, as long as the resulting precipitate redissolves; it then separates on cooling in garnet-dodecahedrons (Mitscherlich). At a gentle heat it gives off half its ammonia, leaving the compound $NH^2.Hg^2Cl^2$, (γ), which is also formed by gently heating mercuric chloride in a stream of ammonia gas, or by distilling mercuric oxide with sal-ammonia. (Mitscherlich.)

Iodide.— $2NH^2.Hg^2I^2 = \frac{Hg''}{H^2}\{N^2I^2$, (η). Red mercuric iodide absorbs ammonia gas and forms this white compound, which however, when exposed to the air, gives off its ammonia and is reconverted into red mercuric iodide. (H. Rose.)

The compound $NH^2.Hg^2I^2$ (δ) is obtained by drenching mercuric iodide with aqueous ammonia, as a white crystalline powder which dissolves in excess of ammonia, leaving a brown powder consisting of hydrated iodide of tetramercurammonium; on evaporating the ammoniacal solution, the compound is deposited in small crystals. It quickly gives off its ammonia when exposed to the air, and is likewise decomposed by water and by acids. (Caillot and Corriol; Rammelsberg.)

Dimercurammonium. $\frac{Hg^2}{H^4}\{N^2$. The *chloride* of this base $\frac{Hg^2}{H^4}\{N^2Cl^2$ (α or ζ), known in pharmacy as infusible white precipitate, *Mercurius precipitatus albus*, is formed by adding ammonia to a solution of mercuric chloride. When first produced it is bulky and milk-white, but, by contact with hot water, or by much washing with cold water, it turns yellow and is converted into hydrated chloride

of tetramercurammonium, $Hg^2N^2Cl^2.2H^2O$. It is readily dissolved by acids, and is especially distinguished from calomel by its behaviour with ammonia, which does not alter white precipitate, whereas calomel is blackened by it. Kane regards this compound as an *amidochloride of mercury*, $Hg^2H^2N^2.Hg^2Cl^2$.

The tetrammonium salts (p. 918), all of which contain water, may be regarded as compounds of dimercurammonium salts with mercuric oxide, e.g. the chloride $Hg^2N^2Cl^2.2H^2O$ as $Hg^2H^2N^2Cl^2.2Hg^2O$. In like manner, *ammoniacal turpethum*, the salt produced by the action of ammonia on mercuric sulphate, and described at p. 920 as a sulphate of tetramercurammonium, $(Hg^2N^2)SO^4.2H^2O$, may be regarded as a basic sulphate of dimercurammonium, $(Hg^2H^2N^2)SO^4.2Hg^2O$.

* The Greek letters in this and the following paragraphs refer to the table on page 921.

A double sulphate of ammonium and dimercurammonium $\left. \begin{smallmatrix} \text{Hg}^2\text{H}^+\text{N}^+ \\ 2\text{H}^+\text{N}^+ \end{smallmatrix} \right\} \text{S}^{\circ}\text{O}^4.3\text{H}^2\text{O}$, (ν), is obtained by adding mercuric oxide by small portions to a cold saturated solution of sulphate of ammonium, waiting each time for the last portion to dissolve, till the liquid begins to show turbidity, from separation of a white basic compound. On leaving this solution to evaporate at ordinary temperatures (if evaporated over the water-bath, it again deposits a white basic compound), the double salt crystallises from it in small white needles, or more definite colourless rhombic crystals, which give off their water at 115° . The salt dissolves easily in sulphate or chloride of ammonium, also in hydrochloric acid, either dilute or concentrated, and in very dilute sulphuric or nitric acid, but is insoluble in strong nitric acid, and is completely decomposed by strong sulphuric acid at the boiling heat.

The double salt is completely decomposed by water, even in the cold, and converted into a heavy, white, earthy powder, consisting of the basic salt, $2(\text{Hg}^2\text{H}^+\text{N}^+)\text{SO}^4.3\text{Hg}^2\text{O}$, (ψ), which likewise separates, when a solution of sulphate of ammonium, saturated with mercuric oxide, is poured into water. It resembles the sulphate of tetramercurammonium (*ammoniacal turpethum*) above mentioned. The latter is also produced by boiling the finely triturated double salt with water, continually renewed as long as it takes up any sulphuric acid.

Another basic compound is obtained by dissolving the above-described double salt in cold dilute sulphuric acid, and adding the solution to an excess of dilute potash-ley; ammonia is then given off, and a white substance separates, which, when washed with water, and dried at 115° , has the composition $\text{Hg}^2\text{H}^+\text{N}^+\text{SO}^4.3\text{Hg}^2\text{O}$, or $(\text{Hg}^2\text{N}^+)\text{SO}^4. \text{Hg}^2\text{O}.2\text{H}^2\text{O}$, (ϕ).

The solution of the last described compound, or of the double salt, in hydrochloric acid, poured into cold dilute potash-ley, kept constantly in excess, forms a white precipitate of $(\text{Hg}^2\text{H}^+\text{N}^+)\text{Cl}^2.3\text{Hg}^2\text{O}$ or $(\text{Hg}^2\text{N}^+)\text{Cl}^2\text{Hg}^2\text{O}.2\text{H}^2\text{O}$, (β). This compound dissolves in boiling aqueous chloride of ammonium, giving off ammonia, and forming a double chloride of ammonium and dimercurammonium, which however has not yet been obtained pure. Finally, by boiling the last-mentioned compound with strong potash-ley till its colour changes from white to yellow, another oxychloride is obtained, having the composition $(\text{Hg}^2\text{H}^+\text{N}^+)\text{Cl}^2.4\text{Hg}^2\text{O}$ or $\text{Hg}^2\text{N}^+\text{Cl}^2.2\text{Hg}^2\text{O}.2\text{H}^2\text{O}$, (α), and by continued boiling for a day with fresh portions of potash-ley, more and more chlorine and nitrogen may be removed, till at last nothing is left but pure mercuric oxide. (Schmiedler.)

Trimercuramine. Hg^2N^2 . This compound is formed by passing dry ammonia gas over precipitated mercuric oxide previously well washed and dried:

The excess of oxide being removed by nitric acid, the trimercuramine is obtained in the form of a dark flea-brown powder, which explodes by heat, friction, percussion, or contact with oil of vitriol, almost as violently as iodide of nitrogen. When cautiously heated with hydrate of potassium, it is decomposed without detonation, yielding ammonia-gas and sublimed mercury. It is also decomposed by hydrochloric, sulphuric and concentrated nitric acid, yielding an ammoniacal and a mercuric salt. (Plantamour, Ann. Ch. Pharm. xl. 115.)

By the action of various ammonia-salts at a boiling heat on mercuric oxide, compounds are obtained, which may be regarded as compounds of trimercuramine with mercuric salts: thus with phosphate of ammonium, the salt $\text{Hg}^2\text{N}^2.\text{Hg}^2\text{P}^{\circ}\text{O}^4.2\text{H}^2\text{O}$ (μ); with the acetate, the compound $\text{Hg}^2\text{N}^2.\text{C}^2\text{H}^2\text{Hg}^2\text{O}^4.4\text{H}^2\text{O}$ (λ) (Hirzel). These compounds may also be regarded as salts of tetramercurammonium (p. 918).

Trimercurammonium. $\left. \begin{smallmatrix} \text{Hg}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}^2$. The only known salt of this base is the

nitrate, $\left. \begin{smallmatrix} \text{Hg}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}^2.(\text{NO}^3)^2.2\text{H}^2\text{O}$, (ρ), which is produced as a white precipitate on mixing a dilute and very acid solution of mercuric nitrate with very dilute ammonia. It might also be regarded as a basic nitrate of mercurammonium, $\left. \begin{smallmatrix} \text{Hg}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}^2.(\text{NO}^3)^2.2\text{Hg}^2\text{O}$, or according to Mitscherlich, as a basic ammonio-nitrate of mercury, $2\text{NH}^2.3\text{Hg}^2\text{O}.\text{N}^2\text{O}^4$.

Tetramercurammonium. Hg^2N^2 . By acting on mercuric oxide with aqueous ammonia, a brown compound is obtained, the so-called mercuramine which may

be regarded as a hydrated oxide of tetramercurammonium $\left. \begin{smallmatrix} \text{Hg}^{\text{N}^2} \\ \text{H}_2 \end{smallmatrix} \right\} \text{O}^{\cdot} \cdot \text{H}_2\text{O}$. It is a strong base and forms definite salts, from which it is separated by acids, without decomposition, at ordinary temperatures. It may also be regarded as oxide of dimercurammonium combined with mercuric oxide, viz. as $\text{Hg}^2\text{H}^{\text{N}^2}\text{O} \cdot 2\text{Hg}^{\text{O}}$, and its salts represented by corresponding formulæ, that is as compounds of mercuric oxide with the chloride, iodide, acetate, &c., of dimercurammonium, or they may be formulated as compounds of mercuric salts with trimercuramine (p. 917). The tetrammonium salts are also produced by the action of ammonium salts on mercuric oxide (Hirzel, lxxxiv. 258), and in other reactions, as will be presently mentioned.

Acetate of Tetramercurammonium. $\text{C}^{\text{H}}(\text{Hg}^{\text{N}^2})\text{O}^{\cdot} \cdot 4\text{H}_2\text{O}$ (λ).—Crystallised compound obtained by treating mercuric oxide with acetate of ammonium. When dried at 100° it leaves a yellowish-white powder.

The *arsenate* is a white salt, obtained by boiling mercuric oxide with arsenate of ammonium.

Bromate. $(\text{Hg}^{\text{N}^2})\text{Br}^{\text{O}^3} \cdot 2\text{H}_2\text{O}$, (ι).—This salt separates slowly from an aqueous solution of mercuric bromate slightly supersaturated with ammonia, bromate of ammonium remaining in solution. When heated in a glass tube, even in very small quantity, it detonates with great violence, metallic mercury being scattered about. (Rammielsberg.)

Carbonate. $(\text{Hg}^{\text{N}^2})\text{CO}^3 \cdot 4\text{H}_2\text{O}$ (χ).—Obtained by passing carbonic acid gas through water, in which hydrate of tetramercurammonium is suspended, as a pale yellow powder, which may be washed with cold water without decomposition (Millon). Hirzel, by boiling finely-divided mercuric oxide with excess of carbonate of ammonium, obtained a salt having the same composition, but with $\frac{1}{2}$ at. water more. It was yellowish-white when dry, turned grey when exposed to light, was not decomposed by potash, but gave off all its nitrogen as ammonia when boiled with aqueous iodide or sulphide of potassium. By treating mercuric oxide with an excess of cold aqueous carbonate of ammonium, Hirzel obtained a white pulverulent salt containing $(\text{Hg}^{\text{N}^2})\text{CO}^3 \cdot \text{H}_2\text{O}$ (π); when exposed to light it quickly decomposed, assuming a grey colour.

Millon's carbonate of tetramercurammonium may be washed with water without decomposition. When perfectly dry, it may be heated without alteration to 130° , but at higher temperatures it gives off a considerable quantity of water. At 145° it assumes a slight brown tint, not however giving off any more water at that temperature; but if the heat be raised to 180 – 200° , more water is given off, together with a large quantity of ammonia; the residue has a deep yellow colour and contains a considerable quantity of carbonic acid, but does not effervesce with acids. This residue is decomposed by strong hydrochloric acid, which eliminates a gas from it, with decrepitation.

Chloride. $\text{Hg}^2\text{H}^{\text{N}^2}\text{Cl}^2 \cdot 2\text{H}_2\text{O}$ (ω).—Obtained by subjecting chloride of dimercurammonium (infusible white precipitate) to prolonged washing with cold water, or better by boiling it with water:

also by treating the chloride of dimercurammonium with potash or soda. It is a heavy granular, yellow powder, which turns white again when treated with sal-ammoniac. (Kane.)

Chromate. $(\text{Hg}^{\text{N}^2})\text{CrO}^4 \cdot 2\text{H}_2\text{O}$, (ν).—A solution of chromate of ammonium does not act on mercuric oxide in the cold; but converts it at the boiling heat into a compound of chromate of tetramercurammonium with 3 at. mercuric chromate $(\text{Hg}^{\text{O}}\text{CrO}^4)$, which when boiled with aqueous iodide or sulphide of potassium, gives off all its nitrogen in the form of ammonia, and when drenched with ammonia, is converted into a lemon-yellow chromate of tetramercurammonium having the composition above indicated.

Hydrate. $\left. \begin{smallmatrix} \text{Hg}^{\text{N}^2} \\ \text{H}_2 \end{smallmatrix} \right\} \text{O}^{\cdot}$, (θ).—This compound is obtained either by treating mercuric oxide with aqueous ammonia, or by heating a salt of tetramercurammonium with a caustic alkali. Yellow mercuric oxide obtained by precipitation is rapidly acted on by ammonia; the red modification but slowly; the product of the action of ammonia on the latter retains the crystalline character of the oxide itself. By washing the hydrate obtained by either process with water, then pressing it between bibulous paper, and drying it over oil of vitriol in a vacuum, or exposing it to a tempera-

ture of 130° ; it is obtained as a brown powder containing $\text{Hg}^{\text{I}}\text{N}^{\text{I}}\left\{\text{H}^{\text{I}}\right\}\text{O}^{\text{I}}\cdot\text{H}^{\text{I}}\text{O}$, (σ). By drying it over quicklime under a bell-jar it is obtained as a yellow substance containing $\text{Hg}^{\text{I}}\text{N}^{\text{I}}\left\{\text{H}^{\text{I}}\right\}\text{O}^{\text{I}}\cdot 4\text{H}^{\text{I}}\text{O}$, (κ). The product prepared from the yellow oxide parts with its water much more readily than that obtained from the red oxide.

The dark brown compound $\text{Hg}^{\text{I}}\text{N}^{\text{I}}\left\{\text{H}^{\text{I}}\right\}\text{O}^{\text{I}}\cdot 2\text{H}^{\text{I}}\text{O}$ (the so-called *anhydrous mercuramine*), which may also be represented as a compound of oxide of dimercurammonium with

mercuric oxide $\text{Hg}^{\text{II}}\text{H}^{\text{II}}\text{N}^{\text{II}}\text{O}\cdot 2\text{Hg}^{\text{II}}\text{O}$, or as a hydramine (i. 197) containing $\text{Hg}^{\text{I}}\left\{\text{H}^{\text{I}}\right\}\text{N}^{\text{I}}\text{O}^{\text{I}}$ is not altered by contact with the air. The yellow more highly hydrated compound, on the other hand, absorbs carbonic acid rapidly from the air and turns white, being converted into carbonate of tetramercurammonium. It is insoluble in *water* and in *alcohol*, gives off ammonia when boiled with *potash*, but requires long boiling to complete the decomposition. The brown compound is decomposed by fusion with *hydrate of potassium* into nitrogen, metallic mercury, and mercuric oxide.

Hydrate of tetramercurammonium dissolves very easily in *acids*, forming the salts of tetrammonium. It expels ammonia very readily from its salts, like lime. It dissolves very easily, with brisk evolution of ammonia gas, in a hot solution of *nitrate of ammonium*, and the solution deposits, on cooling, a considerable quantity of white crystals, which are decomposed by water, yielding a greenish-yellow powder. It dissolves also with equal facility in a hot solution of *sul-ammoniac*, with evolution of ammonia, and separation of a white powder insoluble in water.

Iodate.—By digesting mercuric iodate with ammonia, Millon obtained a salt of variable composition which decomposed at about 180° , with detonation and formation of mercuric iodide.

Iodide. $\text{Hg}^{\text{I}}\text{N}^{\text{I}}\text{I}^{\text{I}}\cdot 2\text{H}^{\text{I}}\text{O}$, (ω). This compound may be formed in several ways.—

1. By heating mercuric iodide with excess of ammonia:

Iodide of hydrogen and dimercurammonium is formed at the same time and dissolves in the hot liquid, while the iodide of tetramercurammonium remains in the form of a brown powder. To obtain it pure, the liquid must be decanted before it begins to deposit crystals, and the brown residue again boiled several times with fresh ammonia, till the filtered liquor no longer deposits crystals on cooling.—2. By passing ammonia-gas over mercuric oxy-iodide:

3. By digesting the chloride of tetramercurammonium in aqueous iodide of potassium (Rammelsberg); adding ammonia to a solution of iodide of mercury and potassium mixed with caustic potash (Nessler, Chem. Gaz. 1856, pp. 446, 463):

This last reaction affords an extremely delicate test for ammonia. A solution of iodide of mercury and potassium is prepared by adding iodide of potassium to a solution of corrosive sublimate till a portion only of the resulting red precipitate is redissolved, then filtering, and mixing the filtrate with caustic potash. The liquid thus obtained produces a brown precipitate with a very small quantity of ammonia, either free or in the form of an ammoniacal salt. The precipitate is soluble in excess of iodide of potassium. (Nessler.)

Iodide of tetramercurammonium is a powder of a brown colour inclining to purple-red. It gives off a small quantity of water at 128° , and if more strongly heated out of contact with the air, it melts to a dark brown liquid, and is then decomposed with a blue light and violent explosion, yielding water, metallic mercury, mercuric iodide, ammonia, and nitrogen, without leaving any residue. Heated with aqueous *sulphide of barium*, it gives off all its nitrogen in the form of ammonia. In a stream of *hydrochloric acid gas*, it turns yellow in parts, gives off white fumes, and at a higher temperature yields a sublimate of ammonio-mercuric iodide, mercuric chloride, chloride of ammonium, and iodide of ammonium. It dissolves easily in warm *hydrochloric acid*, forming a colourless liquid, which, when concentrated, deposits on cooling red crystals of mercuric iodide, and yellow crystals of mercuric iodochloride.

Nitrate. $\text{Hg}^{\text{N}}(\text{NO})^2 \cdot 2\text{H}^2\text{O}$, (like ϵ).—Obtained by mixing a hot dilute solution of mercuric nitrate with a slight excess of ammonia, as a white granular powder, which, when heated, turns yellow, gives off nitrogen and ammonia, then nitrous acid, and finally oxygen and mercury. It is altered by boiling *potash*; dissolves in cold *hydrochloric acid*, and is separated from the solution by water; dissolves sparingly and without decomposition in *nitric* and *sulphuric acids*; dissolves also in *ammonia*, and is partially precipitated from the solution by water. (Soubeiran.)

A yellow crystalline double salt consisting of *nitrate of ammonium* and *tetramercur-*

ammonium, $\left. \begin{matrix} \text{Hg}^{\text{N}}\text{N}^2 \\ 2\text{H}^{\text{N}}\text{N} \end{matrix} \right\} (\text{NO})^4 \cdot 2\text{H}^2\text{O}$ (ξ), is obtained, according to Mitscherlich, by mixing nitrate of trimercurammonium (p. 917) with excess of ammonia, and adding nitrate of ammonium, which dissolves a portion of the salt. As the solution cools and the ammonia evaporates, the double salt separates in crystalline plates.

Oxalate. $\text{C}^2(\text{Hg}^{\text{N}}\text{N}^2)\text{O}^4 \cdot 2\text{H}^2\text{O}$, (τ).—Obtained by digesting mercuric oxalate with excess of ammonia and washing the product till the liquid no longer exhibits any alkaline reaction (Millon); or by digesting mercuric oxide in the cold with oxalate of ammonium (Hirzel). It is a white, loose, amorphous powder, which explodes when heated.

Phosphate. $\left. \begin{matrix} (\text{Hg}^{\text{N}}\text{N}^2) \\ \text{Hg}^2 \end{matrix} \right\} \text{P}^2\text{O}^6 \cdot 2\text{H}^2\text{O}$, (μ).—Obtained by treating mercuric oxide with a boiling solution of tri-ammonic phosphate. It is a white salt which is not decomposed by *potash*, but gives off ammonia when treated with iodide or sulphide of potassium. (Hirzel.)

Sulphate. $(\text{Hg}^{\text{N}}\text{N}^2)\text{SO}^4 \cdot 2\text{H}^2\text{O}$, (σ).—*Ammoniacal turpethum*. This salt, first obtained by Fourcroy, and subsequently analysed by Kane, is prepared by dissolving mercuric sulphate in ammonia and precipitating the solution with water. Ammonia takes up a very large quantity of mercuric sulphate, and when a perfectly saturated solution is left to evaporate in the air or over oil of vitriol, its surface becomes covered with crystalline crusts, consisting of small, hard, highly lustrous crystals of ammoniacal turpethum (Millon). The salt may also be obtained, according to Ullgren, by digesting basic mercuric sulphate (*mineral turpethum*) with sulphate of ammonium till the insoluble portion becomes white.

Sulphate of tetramercurammonium is a white heavy powder, yellowish when dry; when heated it turns brown and is resolved into water, nitrogen, a small quantity of ammonia, and mercurous sulphate. By sulphydric acid it is converted into mercuric sulphide and neutral sulphate of ammonium. It dissolves in hydrochloric and in nitric acid, very slightly in water.

Some of the basic salts already described as produced by the decomposition of sulphate of ammonium and dimercurammonium, may also be regarded as tetramercurammonium-salts (see p. 917).

Mercurous Bases.

Mercurousammonium. $\left. \begin{matrix} (\text{Hg}^2)'' \\ \text{H}^1 \end{matrix} \right\} \text{N}^2$.—The chloride of this base, $(\text{Hg}^2)''\text{H}^1\text{N}^2\text{Cl}^2$, is the black substance formed when dry calomel is exposed to the action of ammonia-gas. When exposed to the air, it gives off ammonia and leaves white mercurous chloride.

Dimercurosammonium. $\left. \begin{matrix} (\text{Hg}^2)'' \\ \text{H}^1 \end{matrix} \right\} \text{N}^2$.—The chloride, $(\text{Hg}^2)''\text{H}^1\text{N}^2\text{Cl}$, is formed by digesting calomel in aqueous ammonia, sal-ammoniac being formed at the same time:

It is grey when quite dry, and is not altered by boiling water. Kane, who analysed this compound, regarded it as *mercurous amido-chloride*, $\text{Hg}^2\text{Cl}^2 \cdot \text{Hg}^2(\text{NH})^2$.

Nitrate of Dimercurosammonium. $(\text{Hg}^2)''\text{H}^1\text{N}^2(\text{NO})^2 \cdot \text{H}^2\text{O}$. This, according to Kane, is the composition of the velvet-black precipitate, known as *Hahnemann's soluble mercury*, which is produced on adding ammonia to a solution of mercurous nitrate. According to C. G. Mitscherlich, on the other hand, the precipitate thus formed has the composition $3\text{Hg}^2\text{O} \cdot \text{N}^2\text{O}^3 \cdot 2\text{NH}^1$, which is that of a nitrate of trimercurosammonium $(\text{Hg}^2)''\text{H}^1\text{N}^2(\text{NO})^2$.

A clearer view of the composition and relations of the ammoniacal mercury-compounds is afforded by the following method of classification, suggested by Mr. G. C. Foster, in which the greater number of these compounds are represented as hydoramines (i. 197), that is, as bodies formed on the mixed type, $\frac{mH^2N}{nH^2O}$, and the rest as hydrochloramines, $\frac{mH^2N}{nHCl}$, hydriodamines, &c. This view of the composition of the ammoniacal mercuric compounds is exhibited in the following table, in which the Greek letters placed under the formulæ correspond to those attached to the names of the compounds in the preceding pages (916-920):

Type $\frac{mH^2N}{nHCl}$			
$\begin{matrix} m = 1 \\ n = 1 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ Cl \end{matrix} \right\}$ α	$\begin{matrix} m = 1 \\ n = 2 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ Br^2 \end{matrix} \right\}$ β
$\begin{matrix} m = 2 \\ n = 2 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \end{matrix} \right\}$ ϵ	$\begin{matrix} m = 2 \\ n = 2 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \end{matrix} \right\}$ ζ
Type $\frac{mH^2N}{nH^2O}$			
$\begin{matrix} m = 1 \\ n = 1 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ O \end{matrix} \right\}$ θ	$\begin{matrix} m = 1 \\ n = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ O^3 \end{matrix} \right\}$ λ
$\begin{matrix} m = 1 \\ n = 2 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ (BrO^2)^2 \end{matrix} \right\}$ ι	$\begin{matrix} m = 1 \\ n = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ O^3 \end{matrix} \right\}$ κ
$\begin{matrix} m = 1 \\ n = 4 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ (PO^2)^2 \end{matrix} \right\}$ μ	$\begin{matrix} m = 2 \\ n = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (SO^2)^2 \end{matrix} \right\}$ ν
$\begin{matrix} m = 2 \\ n = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (NO^2)^2 \end{matrix} \right\}$ ξ	$\begin{matrix} m = 2 \\ n = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ O^3 \end{matrix} \right\}$ π
$\begin{matrix} m = 2 \\ n = 4 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (NO^2)^2 \end{matrix} \right\}$ ρ	$\begin{matrix} m = 2 \\ n = 4 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (SO^2)^2 \end{matrix} \right\}$ σ
$\begin{matrix} m = 2 \\ n = 4 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (NO^2)^2 \end{matrix} \right\}$ τ	$\begin{matrix} m = 2 \\ n = 4 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (CrO^2)^2 \end{matrix} \right\}$ υ
$\begin{matrix} m = 2 \\ n = 6 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (SO^2)^2 \end{matrix} \right\}$ ϕ	$\begin{matrix} m = 2 \\ n = 6 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ (CO^2)^2 \end{matrix} \right\}$ χ
Type $\frac{mH^2N}{nHCl}$			
$\begin{matrix} m = 1 \\ n = 1 \\ o = 1 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ I \\ O \end{matrix} \right\}$ ω	$\begin{matrix} m = 1 \\ n = 1 \\ o = 2 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N \\ Cl \\ O^2 \end{matrix} \right\}$ α'
$\begin{matrix} m = 2 \\ n = 2 \\ o = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \\ O^3 \end{matrix} \right\}$ β'	$\begin{matrix} m = 2 \\ n = 2 \\ o = 3 \end{matrix}$	$\frac{Hg''}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \\ O^3 \end{matrix} \right\}$ β'

The mercurous compounds may be formulated in a similar manner, e.g.:

Chloride of Mercurousammonium	$\frac{(Hg^2)^2}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \end{matrix} \right\}$
Chloride of Dimercurosammonium	$\frac{(Hg^2)^2}{H^2} \left\{ \begin{matrix} N^2 \\ Cl^2 \end{matrix} \right\}$
Nitrate	$\frac{(Hg^2)^2}{(NO^2)^2} \left\{ \begin{matrix} N^2 \\ O^3 \end{matrix} \right\}$

MERCURY-RADICLES, ORGANIC. (Frankland [1852], Ann. Ch. Pharm. lxxxv. 381.—Dünhaupt, Chem. Gaz. 1854, pp. 263-292.—Strecker, Compt. rend. xxxix. 57.—Buckton, Ann. Ch. Pharm. cviii. 103; cix. 218; Chem. Soc. J. xvi. 17.—Frankland and Duppa, *ibid.* xvii. 415.)

Mercury unites with alcohol-radicles of the series, C^nH^{2n+1} , viz. methyl, ethyl, and amyl,—also with allyl C^3H^5 ,—forming compounds into which it enters as a diatomic element. These compounds may, in fact, be regarded as formed from inorganic mercuric compounds, such as the chloride, bromide, &c., by substitution of an alcohol-radicle for either the half or the whole of the chlorine, &c., : thus

Mercuric chloride.

Mercuric chlorethide.

Mercuric ethide.

When both atoms of chlorine, &c., are completely replaced by an alcohol-radicle, the product is an indifferent compound (a neutral mercuric ether) incapable of uniting with acids or acid elements. But when only half of the chlorine, or other chlorous radicle is thus replaced, there results a saline compound, that is to say, a substance which easily undergoes double decomposition, and in which the residue united with the chlorine ($Hg''C^2H^4$ for example), plays the part of a monatomic radicle.

The two kinds of compounds here considered, are in fact related to mercury, in the same manner as mercaptan and ethylic sulphide are related to sulphur,—mercuric ethide, for example, being the ethylic ether of mercuric chlorethide, just as sulphide of ethyl is the ethylic ether of mercaptan.

Mercaptan.

Ethylic sulphide.

Mercuric chlorethide.

Mercuric ethide.

There is, however, this difference between the two classes of compounds, that in mercuric chlorethide and its analogues, in which only 1 at. chlorine &c. is replaced by an alcohol radicle, the remaining chlorous atom is most easily replaced by another chlorous radicle, whereas, in the corresponding sulphur-compounds, the remaining hydrogen-atom, being basylous, is most easily replaced by metals or other basylous elements.

If the mercury in these compounds be regarded as monatomic, those which contain only mercury and an alcohol-radicle must be represented by formulæ of the type HgC^nH^{2n+1} ; and those which contain iodine, chlorine, &c. as compounds of these radicles with mercuric iodide, chloride, &c.; e. g. HgC^2H^4 , *mercurithyl* or *hydrargethyl*; $Hg^2C^2H^4I$ or $HgC^2H^4.HgI$, *iodide*, or rather *mercuriiodide*, of *mercurithyl*, &c.; but the former mode of representation affords a much simpler and more satisfactory view of their relations.

Formation of the Alcoholic Mercury-compounds.—These compounds may be obtained by four different processes:—1. By the action of mercury on the iodide of an alcohol-radicle, under the influence either of diffused daylight or of direct sunshine; combination then takes place, and an iodo-mercuric compound is produced (Frankland, Strecker):

2. By the action of mercuric chloride on a zinc-compound of an alcohol-radicle, the product being an organo-mercuric compound, containing either 2 at. of the alcohol-radicle, or 1 at. alcohol-radicle and 1 at. chlorine, according as one or other of the reagents is in excess (Buckton):

3. By the action of mercuric chloride on the organo-bismuth compounds containing 3 at. of an alcohol-radicle; thus bismutho-triethide (i. 596) treated with mercuric chloride yields bismutho-dichlorethide and mercuric chlorethide (Dünhaupt):

4. By the action of sodium-amalgam on the iodides of the alcohol-radicles in presence of acetic ether (Frankland and Duppa). The reaction is represented by the equation:

The acetic ether appears to take no part in the reaction, but remains in undiminished quantity at the end of the process. Nevertheless, the presence of this or a similar ether (viz. methylic acetate or ethylic formate) is essential to the success of the process, inasmuch as sodium-amalgam does not act on the alcoholic iodides when simply placed in contact or heated with them; neither is the reaction induced by the presence of

ethylic ether, but on adding a few drops of acetic ether, it takes place immediately. The proportion of sodium in the amalgam must be very small, not exceeding 1 pt. to 500 of mercury. If a solid or semi-solid amalgam is used, the reaction proceeds in quite a different manner.

This is by far the best mode of preparing the alcoholic mercury-compounds, yielding in a short time large quantities of the methyl-, ethyl-, and amyl-compounds. Mercuric iodethide and iodomethide are obtained with tolerable facility by the first method above-mentioned; but the corresponding amyl-compound was obtained in this way only in quantities barely sufficient for its identification. On the other hand, to obtain mercuric ethide and methide by the second method, requires the previous preparation of very large quantities of the corresponding zinc-compounds, and the preparation of mercuric amyldide has never been attempted by a similar process, on account of the great difficulty of preparing zinc-amyl. (Frankland and Duppá.)

The mercury-compounds containing 2 at. of an alcohol-radicle, are easily converted, by the action of bromine, chlorine, or iodine, into compounds containing only 1 at. of an alcohol-radicle, e.g.:

A similar action is exerted by acids, e.g. by hydrobromic acid:

With sulphuric acid, in like manner, the products are mercuric sulphatethide,

A precisely similar action is exerted by certain salts. When, for example, mercuric chloride acts upon mercuric ethide, the latter gives up half its ethyl for half the chlorine of the former, producing 2 at. mercuric chloroethide:

On the other hand, the mercuric compounds containing only 1 at. of an alcohol-radicle are easily converted into others containing 2 at. of an alcohol-radicle: thus, mercuric iodethide and zinc-ethyl act upon one another in such a manner as to yield mercuric ethide and iodide of zinc:

The mercury compounds containing 2 at. of an alcohol-radicle are converted into the corresponding zinc-compounds when heated with excess of finely-granulated zinc (Frankland and Duppá, Chem. Soc. J. xvii. 29):

Allyl-compound.

Mercuric Iodallylide. $\text{Hg}''\left\{\begin{matrix} \text{C}^3\text{H}^3 \\ \text{I} \end{matrix}\right.$.—When iodide of allyl is agitated with mercury, a yellow crystalline mass is formed, from which the mercuric iodallylide may be extracted by hot alcohol or ether. The alcoholic solution deposits it on cooling in silvery scales, which turn yellow when exposed to light, especially on drying. It is sparingly soluble in cold alcohol, nearly insoluble in water. It sublimes at 100°, in white shining rhombic plates, melts at 135°, and solidifies on cooling to a yellow crystalline mass. If more quickly and strongly heated, it decomposes for the most part, leaving a carbonaceous residue, and giving off a yellow sublimate.

The alcoholic solution is decomposed by nitrate of silver, the whole of the iodine being separated as iodide of silver; oxide of silver likewise decomposes it, forming iodide of silver and a strongly alkaline solution which, on evaporation, yields a syrupy strongly alkaline mass, soluble in water, and forming salts with acids. This product is probably mercuric allyl-hydrate, or hydrate of mercuriallyl, $\text{Hg}''\left\{\begin{matrix} \text{C}^3\text{H}^3 \\ \text{HO} \end{matrix}\right.$ (Zinin,

Ann. Ch. Pharm. xvi. 393.)

Mercuric iodallylide is easily decomposed by hydriodic acid and by iodine. The following equations represent respectively the action which takes place in each case:

Berthelot's process for preparing tritylene, by means of iodide of allyl, mercury, and hydrochloric acid, depends on the first of these reactions. (Linnemann, Ann. Ch. Pharm. cxxxiii. 133.)

Amyl-compounds.

Mercuric Amylide. $\text{Hg}\left\{\begin{smallmatrix} \text{C}^6\text{H}^{11} \\ \text{C}^6\text{H}^{11} \end{smallmatrix}\right.$ —This compound is obtained by the action of sodium-amalgam on iodide of amyl, in presence of acetic ether. 5 pts. by weight of amylic iodide, and 1 pt. acetic ether are agitated with sodium-amalgam in a vessel externally cooled; the product is distilled over a water-bath to separate the acetic ether, and a current of steam then passed into the retort until about half the heavy liquid has distilled over. The residual liquid, after washing with water and drying over chloride of calcium, consists of pure mercuric amylide.

This compound is a colourless, transparent, mobile liquid, of specific gravity 1.6663 at 0° . It has a very faint amylic odour, and leaves a persistent taste upon the palate, resembling that produced by other organo-mercurial compounds. It cannot be distilled, even in vacuo, without partial decomposition. It can bear a temperature of 140° , but long before its boiling point is reached, mercury separates from it in considerable quantity. It may, however, be distilled with water without decomposition. It is insoluble in water, and very slightly soluble in alcohol, but dissolves readily in ether. Exposed to the air it suffers no oxidation, but when allowed to fall into chlorine, it immediately produces dense white fumes of mercuric chloro-amylide. Brought into contact with solid iodine, it hisses like red-hot iron immersed in water. The reaction with bromine is still more violent. (Frankland and Duppa.)

Mercuric Chloramylicide, $\text{Hg}\left\{\begin{smallmatrix} \text{C}^6\text{H}^{11} \\ \text{Cl} \end{smallmatrix}\right.$, is readily obtained by treating mercuric amylicide with alcoholic solution of mercuric chloride in excess. It closely resembles the iod-amylide (*vid. inf.*) in its properties, is insoluble in water, but very freely soluble in hot alcohol and ether. From its alcoholic solution it crystallises in beautiful hair-like needles, which can be sublimed at a gentle heat without decomposition. It melts at 86° , and has the appearance of a heavy oil, perfectly limpid and colourless. It retains any excess of corrosive sublimate with the greatest obstinacy, repeated washings with alcohol and water not being sufficient to remove it. It may, however, be purified by dissolving it repeatedly in alcohol and reprecipitating with water. (Frankland and Duppa.)

Mercuric Iodamylicide. $\text{Hg}\left\{\begin{smallmatrix} \text{C}^6\text{H}^{11} \\ \text{I} \end{smallmatrix}\right.$.—An ethereal solution of mercuric amylicide, treated first with alcoholic solution of iodine, and then with solid iodine, nearly solidifies to a crystalline mass of mercuric iod-amylide, iodide of amyl being at the same time produced:

On washing the crude product with weak alcohol, pressing between folds of blotting paper, and recrystallising from hot alcohol, mercuric iod-amylide is deposited in small pearly scales, which are not very soluble in alcohol, but freely soluble in ether. If a few drops of alcoholic potash are added to a boiling saturated alcoholic solution of these crystals, and the liquid left to cool, no crystals appear for some time; but ultimately large pearly plates are deposited, which have the same composition as the small scaly crystals above mentioned, and reproduce them when washed with water and redissolved in alcohol. Mercuric iod-amylide is slightly soluble in boiling water, and separates therefrom on cooling in minute crystals which appear as an opalescent cloud in the liquid. It melts at 122° , and on cooling solidifies to a white crystalline mass, having the appearance of stearin; at 140° it begins to turn yellow from formation of mercurous iodide. In a moderately heated current of air, it may be sublimed without change. It is but partially decomposed by alcoholic potash. Heated with zinc to 130° in a sealed tube it yields zinc-amyl and zinc-amalgam. (Frankland and Duppa.)

Ethyl-compounds.

Strecker, by acting on iodide of ethyl with mercury, obtained the compound $\text{Hg}(\text{C}^2\text{H}_5)\text{I}$, originally designated as *iodide of mercuriethyl*, or *iodide of hydrargethyl*, but now called *mercuric iodethide*. Dünhaupt obtained the corresponding chlorine- and bromine-compounds, by decomposing bismutho-triethide with mercuric chloride or bromide, and prepared therefrom several of the other salts. Buckton obtained mercuric ethide $\text{Hg}(\text{C}^2\text{H}_5)_2$, by the action of zinc-ethyl on mercuric iodethide or on mercuric chloride (pp. 921, 922); and lastly Frankland and Duppa have shown that this compound may be more easily obtained by the action of sodium-amalgam on iodide of ethyl, in presence of acetic ether.

Mercuric Bromethide. $\text{Hg}(\text{C}^2\text{H}_5)_2\text{Br}$.—Obtained by the action of mercuric bromide on bismutho-triethide, or by treating mercuric hydro-ethide with hydrobromic

acid, or an alcoholic solution of the hydro-ethide with alcoholic bromine. It resembles the chlorethide. (Dünhaupt.)

Mercuric Carbonethide. *Carbonate of mercur ethyl.*—Prepared by decomposing the chlorethide with carbonate of silver at a gentle heat. It crystallises with difficulty and is easily decomposed by heat. Acids decompose it, with evolution of carbonic anhydride. (Dünhaupt.)

Mercuric Chlorethide. $\text{Hg}^{+}(\text{C}^2\text{H}^3)\text{Cl}$.—Obtained by the action of mercuric chloride on bismutho-triethide (Dünhaupt); by precipitating the aqueous solution of the nitrethide with chloride of sodium (Strecker); and by treating mercuric ethide with alcoholic solution of mercuric chloride in excess (Frankland and Duppa). It is nearly insoluble in water, dissolves sparingly in ether, and in cold alcohol, but freely in boiling alcohol, and crystallises therefrom in light iridescent laminae, having a silvery lustre. When heated to 40° it sublimates in thin laminae, without previous fusion, but at 100° it melts to a clear oily liquid, and then evaporates completely. Heated on platinum-foil it burns with a faint flame, diffusing a very unpleasant odour. (Dünhaupt.)

Mercuric Cyanethide. $\text{Hg}^{+}(\text{C}^2\text{H}^3)\text{Cy}$.—Formed by saturating an alcoholic solution of mercuric hydrethide with strong hydrocyanic acid. Crystallises readily. Very volatile; when heated in a tube, it emits a vapour which has an extremely repulsive odour, attacks the respiratory organs strongly, and appears to be highly poisonous; a carbonaceous residue is left in the tube. The cyanide dissolves readily in alcohol and ether. (Dünhaupt.)

Mercuric Ethide. $\text{Hg}^{+}(\text{C}^2\text{H}^3)^2$.—This compound is prepared:—1. By the action of zinc-ethyl on mercuric iodethide. Dry pulverised mercuric iodethide is added by small quantities to zinc-ethyl contained in a retort through which a stream of coal-gas is passing, the mixture being incorporated by stirring, and, as soon as the zinc-ethyl is saturated—which may be known by the stirring rod ceasing to fume on exposure to the air—the product is distilled till nothing but gases pass over. The distillate, which is a heavy liquid, mixed with a little ether, is then redistilled with a slight excess of zinc-ethyl, to ensure complete decomposition of the iodethide, then washed with hydrochloric acid, and afterwards with water, and rectified (Buckton).—2. By heating zinc-ethyl with mercuric chloride, avoiding an excess of the latter, as otherwise mercuric chlorethide will be formed: the slight excess of zinc-ethyl is decomposed by water, and the separated oxide of zinc dissolved out by dilute hydrochloric acid. (Buckton.)

3. A mixture of 16 pts. by weight of iodide of ethyl and 1 pt. of acetic ether is poured upon sodium-amalgam, the flask being alternately agitated to promote the reaction, and plunged into cold water to moderate the rise of temperature. The completion of the reaction is known by the subsidence of the temperature, and the absence of more than traces of precipitated iodine, when a few drops of the clear liquid remaining in the flask are boiled with nitric acid. When the quantity of iodide of sodium formed has been increased so far as to render the ethereal liquid pasty, thereby preventing a sufficiently intimate contact with the amalgam, it is advisable to place the flask in a water-bath, and distil off the more volatile portion of the contents, to be again acted on by fresh amalgam.* If this distillation be deferred till the residue has become decidedly thick and pasty, it will not be necessary to repeat it, as the distillate will remain sufficiently fluid up to the termination of the reaction. The product mixed with water separates into two layers, the ethereal liquid either floating or sinking in the aqueous solution of iodide of sodium, according to the degree of concentration or the latter. It is then successively treated with alcoholic potash, washed with water, dried over chloride of calcium, and rectified. (Frankland and Duppa.)

4. Buckton likewise obtained mercuric ethide by the action of cyanide of potassium on the iodethide:

but this mode of preparation is not advantageous, being attended with considerable loss.

Mercuric ethide is a transparent colourless liquid, having a faint ethereal odour, insoluble in water, sparingly soluble in alcohol, easily in ether. Specific gravity = 2.46. Boiling point 158° to 160° (Buckton); 159° (Frankland and Duppa). Vapour-density, obs. = 9.97; calc. (2 vol.) = 9.4.

Mercuric ethide burns with a smoky flame, giving off a large quantity of mercurial vapour. When poured into chlorine gas, it bursts into flame and is almost entirely destroyed. It acts violently also with iodine or bromine, forming mercuric iodethide or bromethide; if the action be conducted under water, ethyl, or its products of decom-

* In the preparation of mercuric amyliide (p. 923), this intermediate distillation is not necessary, as the liquid retains sufficient fluidity to allow the action to complete itself.

position are eliminated: but if the liquid is kept cool by a freezing mixture, the nascent ethyl unites with the bromine:

With excess of alcoholic mercuric chloride, it yields mercuric chlorethide (p. 923).

With hydrochloric or sulphuric acid, it yields hydride of ethyl and mercuric chloride or sulphatethide:

Sodium slowly decomposes mercuric ethyl, forming a bulky grey spongy mass, which is very liable to explode from slight causes, and instantly takes fire on coming in contact with the air. On applying a gentle heat, a violent evolution of gas takes place, consisting of ethyl and hydride of ethyl, sodium-ethyl being probably formed in the first instance, and then decomposed by the heat. (Buckton.)

Heated with excess of finely granulated zinc to 100° in a sealed tube, it yields zinc-ethyl and zinc-amalgam. Heated with bismuth, it yields in like manner bismuth-ethyl, but the decomposition is not complete. Cadmium heated with mercuric ethide to 100° – 130° , becomes amalgamated, and forms a considerable quantity of cadmium-ethyl. Gold likewise become amalgamated, but forms no trace of an organo-metallic compound. Mercuric ethide is likewise decomposed when heated to about 150° , with copper, iron, or silver, the copper becoming slightly amalgamated, and inflammable gas being given off; but the decomposition appears to be due to the heat alone, independently of any specific action of the metal. No organo-metallic compound is formed in either case. (Frankland and Duppa.)

Mercuric Ethyl-hydrate. $\text{Hg}^2\left\{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{HO} \end{matrix}\right\}$. *Hydrate of Mercurethyl.*—Obtained by decomposing a boiling alcoholic solution of the chlorethide with oxide of silver, then filtering, distilling off the alcohol, and evaporating in vacuo. It then remains as a colourless oil, which is strongly alkaline and blisters the skin. It decomposes ammonium-salts, but not the salts of potassium or magnesium, and forms precipitates with the salts of aluminium, zinc, tin, copper, gold, and platinum. With a large excess of sulphydric acid, it forms a white precipitate which after a while turns yellow, brown, and black. With metallic zinc it forms zinc-ethyl, and amalgam of zinc. It dissolves in acids, forming crystallisable salts, viz. mercuric chlorethide, nitrethide, &c.

Mercuric Iodethide. $\text{Hg}^2(\text{C}^2\text{H}^5)_2\text{I}_2$.—This compound is obtained by the reactions above-mentioned (pp. 921, 922), or by mixing an alcoholic solution of the ethyl-hydrate with a slight excess of alcoholic iodine. It is insoluble in water, but soluble in boiling alcohol and ether, and separates on cooling in white shining laminae. It dissolves also without decomposition in caustic ammonia and potash. It sublimes at 100° without decomposition, but requires a much stronger heat to melt it. It is decomposed by direct sunshine: hence in preparing it by the action of mercury on iodide of ethyl, the vessel must be exposed only to diffused daylight. (Dünhaupt, Strecker.)

Mercuric Nitrethide. $\text{Hg}^2\left\{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{NO} \end{matrix}\right\}$. *Nitrate of Mercurethyl.*—Nitrate of silver added to a solution of the iodethide, forms a precipitate of iodide of silver, and a solution of mercuric nitrethide, which yields colourless prisms by evaporation. (Strecker.)

Mercuric Phosphatethide, or Phosphate of Mercurethyl, is obtained by treating the chlorethide with phosphate of silver. It is very soluble in water, and remains on evaporation as a viscid diaphanous mass. (Dünhaupt.)

Mercuric Sulphatethide. $\text{Hg}^2\left\{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{SO}^4 \end{matrix}\right\}$. *Sulphate of Mercurethyl.*—Prepared by decomposing the chlorethide with sulphate of silver. Crystallises from alcohol in shining laminae.

Mercuric Sulphethide. $\text{Hg}^2\left\{\begin{matrix} \text{C}^2\text{H}^5 \\ \text{S} \end{matrix}\right\}$.—This compound separates as a yellowish-white pulverulent precipitate on adding sulphide of ammonium to an alcoholic solution of the chlorethide. It is very soluble in alcohol, ether, and sulphide of ammonium, and separates from the ethereal solution in the crystalline state, but always mixed with sulphide of mercury. The alcoholic solution is also decomposed by evaporation, depositing sulphide of mercury.

Methyl-compounds.

Mercuric Iodomethide. $\text{Hg}^2(\text{CH}^3)_2\text{I}_2$.—This compound was discovered by Frankland (Ann. Ch. Pharm. lxxxv. 380), who obtained it originally by the action

of mercury on iodide of methyl in sunshine. In about a week, the liquid solidifies into a colourless crystalline mass, and by treating this mass with ether, the mercuric iodethide is dissolved, and may thus be separated from the remaining metallic mercury and the small quantity of iodide of mercury formed at the same time. Very little gas is given off during the reaction. Mercuric iodomethide is, however, more easily obtained by the action of iodine on an alcoholic solution of mercuric methide.

Mercuric iodomethide is a white solid body, insoluble in water, but dissolving pretty readily in common alcohol, more easily in *mythylic alcohol*, and very easily in ether and in iodide of methyl. By spontaneous evaporation of either of these solutions, the iodide is obtained in small, nacreous, crystalline laminae. At ordinary temperatures, it is slightly volatile, emitting a peculiar and unpleasant odour; the vapour when inhaled leaves a nauseous taste on the palate which lasts for several days. At 100°, the iodide is much more volatile, the crystals disappearing completely when exposed to a current of air at that temperature. At 143°, it melts and sublimes without decomposition, condensing in extremely thin, shining, crystalline laminae.

Mercuric Methide. $\text{Hg}(\text{CH}^3)_2$. *Mercuriomethyl. Hydrargomethyl.* Discovered by Buckton (Proc. Roy. Soc. ix. 91), who obtained it by distilling mercuric iodomethide with cyanide of potassium, hydrate of potassium, or lime. The best product is obtained with the cyanide. A mixture of this salt with mercuric iodomethide, after being well triturated in a mortar, is distilled by small portions over a lamp. Gaseous products are then evolved; iodide of potassium is formed; cyanogen is set free and remains in the form of paracyanogen; and mercuric methide passes over in the form of a heavy liquid, which may be purified by washing with water and rectification over chloride of calcium. The essential part of the reaction is represented by the equation:

Frankland and Duppa prepare mercuric methide by the action of sodium-amalgam on iodide of methyl, in presence of acetic ether. The mode of preparation is exactly the same as that already described (p. 925) for the preparation of mercuric ethide, a small Liebig's condenser being, however, attached to the neck of the flask, to arrest the vapour of iodide of methyl, which would otherwise be carried away by the escaping gas. At the end of the operation, the residues in the flasks are mixed with water and distilled in an oil-bath, the temperature of which need not be raised above 110°, and the ethereal distillate, after separation from the water which accompanies it, is agitated with alcoholic potash to remove acetic ether, and finally purified by washing with water.

Mercuric methide is a colourless, strongly refracting liquid, having a faint and somewhat mawkish taste. Specific gravity 3.069. Boiling point between 93° and 96°. Vapour density, obs. = 8.29; calc. = 7.97. It is insoluble in water, very soluble in alcohol and in ether, dissolves phosphorus, caoutchouc, and resins easily, sulphur in small quantity.

Mercuric methide is very inflammable and burns with a bright flame, giving off vapour of mercury. It does not unite directly with oxygen, chlorine, or other electro-negative elements, but is completely decomposed by them. Iodine and bromine act upon it very energetically, eliminating methyl-gas and forming mercuric, iodo-, or bromo-methide:

It also forms mercuric iodomethide when heated with mercuric iodide.

With stannic chloride it forms a crystalline compound, which is decomposed by water, with formation of mercuric chloromethide and a soluble tin-salt. With strong sulphuric or hydrochloric acid, it acts like mercuric ethide (p. 925), giving off marsh-gas, and forming crystals of mercuric chloromethide or sulphatomethide. With dilute acids and metallic zinc, it yields metallic mercury and gaseous products; its salts (mercuric iodomethide, &c.) are decomposed in like manner (Buckton). Heated with metallic zinc alone, it yields zinc-ethyl and zinc-amalgam (Frankland and Duppa). With trichloride of phosphorus, it forms mercuric chloromethide.

Mercuric Nitromethide. $\text{Hg}\left\{\begin{smallmatrix} \text{CH}^3 \\ \text{NO}^2 \end{smallmatrix}\right.$ Nitrate of Hydrargomethyl.—Obtained

by treating an alcoholic solution of mercuric iodomethide with nitrate of silver, and evaporating the filtrate in vacuo. Crystallises in nacreous laminae, containing $2\text{Hg}(\text{CH}^3)\text{NO}^2 \cdot \text{H}^2\text{O}$, very soluble in water, sparingly in alcohol. At 100°, it melts to a colourless liquid which solidifies in a crystalline mass on cooling. Its solution is not precipitated by potash or baryta-water. Hydrochloric acid and soluble chlorides precipitate mercuric chloromethide in nacreous laminae. (Strecker, Ann. Ch. Pharm. xcii. 79.)

Mercuric Oxymethide, or *Oxide of Hydrargomethyl*, is produced by the action of ammonia or the fixed alkalis on mercuric iodomethide. It is dissolved by an excess of either of these reagents, and the solutions yield with sulphide of ammonium a flocculent precipitate of the corresponding *sulphide*, having a faint yellowish colour, and a peculiar and most intolerable odour. (Frankland.)

MEROXENE. Syn. with Biotite. (See MICA.)

MESACONIC ACID. $C^4H^4O^4$. *Citraconic acid* (Gottlieb, Ann. Ch. Pharm. lxxvii. 268; Pebal, *ibid.* lxxviii. 129; Baup, *ibid.* lxxxi. 96).—An acid obtained by boiling a weak solution of citraconic acid for half an hour with about the sixth of its volume of nitric acid. The reaction takes place quietly, and on cooling the acid is deposited in a porcelain-like mass. A certain quantity of a nitro-compound is produced at the same time, from which the acid may be purified by treatment with animal charcoal.

Mesaconic acid forms a mass of fine lustrous needles, difficultly soluble in cold, but readily so in hot water, and also in alcohol and in ether. It melts at 200° to a clear liquid, which solidifies to a crystalline mass. It reddens litmus and decomposes carbonates. Heated with concentrated *hydriodic acid* to 140° — 160° , it separates iodine and forms *pyrotartaric acid*; it is also converted into this acid by *sodium-amalgam*. With *bromine*, at 60° — 80° , it forms *mesodibromo-pyrotartaric acid*, $C^4H^2Br^2O^4$. (Kekulé, Ann. Ch. Pharm. Suppl. ii. 85.)

Mesaconic acid is dibasic, its salts having the formulæ $C^4H^2M^2O^4$ and $C^4H^3MO^4$. They are almost all crystallisable.

The *neutral barium-salt*, $C^4H^2Ba^2O^4 \cdot 4H^2O$, is obtained by saturating the acid with carbonate of barium. It forms monoclinic prisms, which are unalterable in the air, and give off the greater part of their water of crystallisation at 100° . The *acid barium-salt*, $C^4H^3Ba^2O^4 \cdot 2H^2O$, forms hexagonal plates of a pearly lustre, which persistently retain an excess of acid, from which they are freed with difficulty. The *neutral calcium-salt*, $C^4H^2Ca^2O^4 \cdot H^2O$, forms small agglomerated needles soluble in 16 pts. of water. The *neutral silver-salt* is a crystalline precipitate, difficultly soluble in water. The *acid silver-salt*, $C^4H^3AgO^4$, is obtained in needles by dissolving the neutral salt in solution of mesaconic acid and evaporating. E. A.

MESACONIC ETHER. $C^4H^4O^4 = C^4H^4(C^2H^3)^2O^4$. Obtained by distilling a mixture of mesaconic acid, sulphuric acid, and alcohol. It is a colourless mobile liquid, with an agreeable fruity odour and bitter taste. Its density is 1.043, and it distils at 220° without alteration. It is not attacked by ammonia. Boiled with baryta-water it yields alcohol and mesaconate of barium. E. A.

MESITE. An oxygenated oil, very mobile, boiling above 70° , and soluble in 3 pts. of water, said to be obtained by distilling lignone with sulphuric acid. (Wiedemann and Schweitzer.)

MESITENE. Another very mobile oil, boiling at 63° , and soluble in 3 pts. of water, obtained in like manner.

MESITIC ALCOHOL. A name given to acetone, on the supposition that it is an alcohol containing the radicle *mesityl*, C^3H^3 , isomeric with allyl.

MESITIC ALDEHYDE. C^3H^4O . A body isomeric with acrolein, produced, together with trinitromesitylene, by heating acetone with half its bulk of strong nitric acid. The action is extremely violent, so that it is necessary to cool the vessel as soon as effervescence begins, then heat it again and repeat this treatment several times. When the action is completed, an oil separates, consisting of mesitic aldehyde mixed with trinitromesitylene.

Mesitic aldehyde is lighter than water, has a sweet pungent odour, is very slightly soluble in water, but dissolves instantly in caustic potash, yielding a yellowish-brown liquid. It absorbs ammonia gas with great avidity, forming a brown resinous mass, which dissolves in water, the solution yielding by spontaneous evaporation crystals of *mesitic aldehyde-ammonia*. Nitrate of silver added to the solution of these crystals, forms a yellow precipitate, which blackens when heated; the reduction is accelerated by the addition of a few drops of potash. (Kane, Pogg. Ann. xli. 491.)

MESITIC CHLORAL. Syn. with Dichloracetone. (See ACETONE, i. 30.)

MESITIC ETHER. Syn. with Oxide of Mesityl. (See MESITYL.)

MESITIN-SPAR. $(Mg;Fe)CO^2$. *Brunnerite*, *Pistomesite*.—This mineral occurs in rhombohedral crystals isomorphous with spathic iron ore and magnesite. $R : R = 107^\circ 23'$; $\alpha R : R = 136^\circ 52'$. Length of principal axis = 0.81135. Observed planes, R , — $\frac{1}{2}$ R . Cleavage rhombohedral, perfect. Crystals often imbedded. Also massive, granular, and fibrous. Hardness = 4 to 4.5. Spe-

cific gravity = 3 to 3.63. Colourless, whitish, yellowish, and often brown on exposure. Transparent to subtranslucent. Brittle. The mineral may be regarded as a mixture of the isomorphous carbonates MmgCO_3 and FfeCO_3 , the proportion of the former varying from 89.7 to 42.7 per cent., and that of the latter from 5.1 to 57.2 per cent. Some specimens also contain small quantities of calcium and manganese. Mesitinspar occurs in chlorite slate at St. Gothard; also in the Zillerthal; at Hall, and elsewhere in the Tyrol, and at Traversella in Piedmont. The species includes much of the so-called *brown spar*. (Dana, ii. 443.)

MESITYL. A hypothetical monatomic radicle, supposed by Kane to exist in acetone (regarded as $\text{C}^{\text{H}^3}\text{O}$), and in certain products obtained from it.

Chloride of Mesityl. $\text{C}^{\text{H}^3}\text{Cl}$, is produced by passing hydrochloric acid into acetone, which absorbs it in large quantity; or better by adding 2 pts. of pentachloride of phosphorus, by small portions, to 1 pt. of acetone, properly cooled, then adding water, which separates the chloride of mesityl in the form of an oily liquid heavier than water. It is resolved by heat into hydrochloric acid and mesitylene. Alcoholic potash converts it into oxide of mesityl. (Kane, Pogg. Ann. xlv. 476.)

Hydrate of Mesityl. $\text{C}^{\text{H}^3}\text{H}\text{O}$. Syn. with Acetone.

Iodide of Mesityl. Oily liquid insoluble in water, obtained by distilling acetone with iodine and phosphorus. It has not been analysed. (Kane.)

Oxide of Mesityl or Mesityl ether. $(\text{C}^{\text{H}^3})_2\text{O}$.—Produced: 1. By the action of alcoholic potash in excess on chloride of mesityl.—2. Together with many other products, by the action of strong sulphuric acid on acetone (Kane).—3. By the action of lime on acetone. Acetone left for several weeks in contact with quicklime, and then subjected to fractional distillation, yields, between 100° and 250° , a mixture of oxide of mesityl, boiling at about 129° , and phorone, $\text{C}^{\text{H}^4}\text{O}$, boiling at 290° , which may easily be separated by rectification. (Fittig, Ann. Ch. Pharm. ex. 23.)

Pure oxide of mesityl is a colourless oil, smelling like peppermint. Specific gravity 0.818 at 23° . Boiling point (corrected) 131° . Vapour-density, obs. = 3.67; calc. 3.39 (Fittig). It burns with a very bright flame (Kane). It is insoluble in water, mixes in all proportions with alcohol and ether; is converted by nitric acid into a brown resinous mass, and by chlorine into a heavy oil, which appears to have the composition $\text{C}^{\text{H}^3}\text{Cl}_2\text{O}$. (Fittig.)

Mesityl-hypophosphorous acid.—An acid contained, according to Kane, in the syrupy residue obtained by distilling acetone with iodine and phosphorus. This residue solidifies, on cooling, to an amaranthine mass, and yields, by saturation with carbonate of barium, a salt containing 20.0 per cent. carbon, 3.8 hydrogen, and 43.8 baryta, whence Kane deduces the formula $\text{Pb}_2\text{O.C}^{\text{H}^3}\text{O}$ (calc. 20.7 carbon, 3.45 hydrogen, and 44.02 baryta).

Mesityl-phosphoric acid.—An acid produced by treating acetone with phosphoric acid. The resulting liquid neutralised with bases, yields soluble salts. The sodium-salt forms small rhomboidal laminae, which, when exposed to the air, become opaque, and give off part of their water. When heated, they melt in their water of crystallisation, and ultimately leave a white mass, which, at a higher temperature, swells, blackens, and burns, leaving phosphate of sodium. The salt was found to contain 48.8 per cent. sodic phosphate, and 29.0 water, agreeing approximately with the formula $\text{PNaO}.3\text{C}^{\text{H}^3}\text{O}.4\text{H}_2\text{O}$, which requires 49.9 sodic phosphate, and 28.21 water. (Kane.)

Mesityl-sulphuric acids.—Kane found, among the products of the action of sulphuric acid upon acetone, two acids analogous in composition to ethyl-sulphuric acid.

1. When acetone is mixed with twice its volume of strong sulphuric acid, the liquid becomes very hot, assumes a dark brown colour, and gives off a large quantity of sulphurous anhydride; and if it be mixed after cooling with 2 or 3 volumes of water and neutralised with chalk, a deliquescent mass is obtained, in which small prisms may be distinguished, yielding, according to Kane's analysis, 70.5 per cent. calcic sulphate, 18.5 carbon, 3.3 hydrogen, and 7.9 oxygen, numbers which Kane represents by the formula $\text{C}^{\text{H}^3}\text{O}.3\text{CaSO}_4$.

2. By treating 2 vol. acetone with 1 vol. sulphuric acid, and diluting with water when cold, Kane obtained another acid, the calcium-salt of which was found to contain 23.7 per cent. lime, 30.8 carbon, and 4.4 hydrogen, and may be represented, according to Kane, by the formula $2\text{C}^{\text{H}^3}\text{O}.3\text{CaSO}_4$.

Gerhardt made several attempts to obtain these acids by the processes above described, but did not obtain a trace of either of them; he considers it probable that the only acid produced by the action of oil of vitriol on acetone is methyl-sulphuric acid. (Traité, i. 704.)

MESITYLENE or **MESITYLOL**. C^9H^{12} . (Kane, Pogg. Ann. xl. iv. 474.—Hofmann, Chem. Soc. J. ii. 104.—Cahours, Compt. rend. xxiv. 255; Chem. Soc. J. iii. xvii.)—A hydrocarbon, isomeric with cumene, produced by the action of sulphuric acid upon acetone. To prepare it, 2 vol. acetone are distilled with 1 vol. strong sulphuric acid, the heat being carefully regulated. Two layers of liquid then collect in the receiver, the upper consisting of very impure mesitylene, and the lower containing sulphurous and acetic acids, resulting from a secondary decomposition. The upper layer is rectified, first over the water-bath to separate undecomposed acetone, and then over the naked fire. But the product thus obtained does not exhibit a constant boiling point, and requires to be purified by numerous rectifications (Hofmann), and final distillation over phosphoric acid. (Cahours.)

Mesitylene is a very light, colourless substance, having a slight alliaceous odour. It boils between 155° and 160° (Hofmann), between 162° and 164° (Cahours). Vapour-density, obs. = 4.345 to 4.282 (Cahours); calc. = 4.160.

Mesitylene burns with a bright, but very smoky flame. It dissolves iodine, forming a dark brown liquid which is not altered by exposure to sunshine. With bromine and chlorine, it forms crystalline substitution-products. Boiling nitric acid converts it into mesitic aldehyde (Kane). A mixture of fuming nitric and fuming sulphuric acids converts it immediately, and without rise of temperature, into trinitromesitylene (Cahours). It is likewise decomposed by strong sulphuric acid, but not by aqueous alkalis (Kane). Fuming sulphuric acid converts it into mesitylene-sulphuric acid $C^9H^{12}SO^2$. (Cahours.)

Derivatives of Mesitylene.

Tribromomesitylene. $C^9H^3Br^3$.—When bromine is added drop by drop to mesitylene, waiting each time till the heat evolved has subsided, and taking care to keep the mesitylene in excess, a white crystalline compound is formed, which may be freed from hydrobromic acid by washing with water, in which it is perfectly insoluble. Two or three crystallisations from boiling alcohol render it absolutely pure. It forms white needles, which volatilise without decomposition, and are not changed by boiling with potash or ammonia. (Hofmann.)

Trichloromesitylene. $C^9H^3Cl^3$.—To prepare this compound, chlorine gas is passed through mesitylene till the liquid solidifies in an acicular mass, which is then dissolved in hot ether and crystallised by cooling, the undecomposed mesitylene remaining in the mother-liquid. The product is purified by recrystallisation, and the crystals dried between paper, but not in contact with the air.

It forms white, shining, four-sided prisms, resembling sulphate of quinine, volatilising only at a strong heat, but without decomposition. They may also be sublimed without alteration in dry ammoniacal gas, and are not decomposed by alcoholic potash. (Kane.)

Nitromesitylene. $C^9H^{11}NO^2$.—Formed by treating mesitylene with fuming nitric acid, not in excess, and carefully cooling the mixture during the action. This compound, when treated with an alcoholic solution of potash, becomes heated and evolves two products on distillation. One of these is a liquid, which is produced in very small quantity only, and exhibits the properties of an alkaloid; the other, which is solid, dissolves very readily in alcohol, and separates from it by spontaneous evaporation in very fine tabular crystals; it is isomeric with nitromesitylene. (Cahours.)

Dinitromesitylene. $C^9H^9(NO^2)^2$.—Obtained by boiling mesitylene with moderately strong nitric acid. After a few distillations, the whole of the mesitylene is converted into a crystalline compound, which may be purified by washing with water and recrystallisation from alcohol. With dilute nitric acid a less definite result is obtained, the mesitylene being converted, after repeated distillation, into a yellow oil, which shows a tendency to crystallise, but appears to be a mixture.

This compound crystallises in fine needles, often several inches long, and in appearance resembling those of trinitromesitylene (*vid. inf.*). It volatilises without decomposition, and dissolves with great facility in alcohol. (Hofmann.)

Nitromesidine. $C^9H^{11}N^2O^2 = C^9H^{11}(NO^2)N$. (Maule, Chem. Soc. Qu. J. ii. 116.)—A base obtained by the action of sulphydric acid on dinitromesitylene:

When an alcoholic solution of dinitromesitylene is submitted to the action of sulphydric acid, the liquid assumes a dark colour and deposits gradually a large quantity of sulphur, the odour of the sulphydric acid being at the same time destroyed. This treatment is continued for several days, till the sulphydric acid is no longer decomposed. On the addition of hydrochloric acid, sulphur is again precipitated, and on separating this by filtration, a clear liquid is obtained, which when mixed with potash

or ammonia, yields a copious precipitate of impure nitromesidine. By repeatedly dissolving this impure product in hydrochloric acid and reprecipitating by an alkali, small quantities of still adhering sulphur are separated, and the substance gradually assumes a bright yellow colour. One or two crystallisations from alcohol now suffice to render it absolutely pure.

Nitromesidine forms long needle-shaped crystals of a golden yellow colour. It melts below 100° , and solidifies on cooling in a mass of radiated needles; volatilises without decomposition at 100° , giving off a vapour which burns with a bluish flame; dissolves very readily in alcohol and ether, and sparingly in water, to which it imparts a faint yellow colour. The solutions have an unpleasant bitter taste, and are neutral to test paper.

Bromine acts violently on nitromesidine, forming a dark oily liquid. An alcoholic solution of nitromesidine yields with chlorine, a pinkish solid substance soluble in boiling ether.

Nitromesidine dissolves readily in acids, forming crystalline salts, which however are very unstable, all those yet obtained, excepting the phosphate and the platinum-salt, being decomposed by mere contact with water. They are soluble in alcohol, and their solutions have an acid reaction.

The hydrochlorate, $C^6H^3N^2O^2.HCl$, forms colourless needles.

The chloroplatinate, $2(C^6H^3N^2O^2.HCl).PtCl_4$, is precipitated in yellow crystals on mixing a hot solution of platonic chloride in excess, with a saturated solution of hydrochlorate of nitromesidine.

The nitrate is very unstable, being decomposed, with evolution of red nitrous fumes, when its aqueous solution is evaporated down to a certain point.

The phosphate, $3C^6H^3N^2O^2.PH^3O_4$, crystallises in orange-coloured laminae. When nitromesidine is dissolved in a very large excess of phosphoric acid, an acid salt is obtained, apparently containing only 1 at. nitromesidine.

The sulphate forms small silky crystals.

Trinitromesitylene. $C^6H^3(NO^2)^3$.—Obtained by treating mesitylene with a mixture of fuming nitric and sulphuric acids, its formation taking place immediately, and without rise of temperature. It is crystalline, and sublimes at a gentle heat in dazzling white needles. It is very slightly soluble in boiling alcohol and ether, but dissolves easily in acetone. It is very slowly acted on by sulphuric acid, only a small quantity of an alkaline body being formed after the lapse of several weeks. (Cahours.)

MESITYLENE-SULPHURIC ACID. *Sulphomesitylic acid.* $C^6H^3SO^4$.—This acid is easily formed by dissolving mesitylene in fuming sulphuric acid, the brown liquid, when exposed to the air, gradually solidifying to a crystalline mass. When saturated with carbonate of lead, it forms the lead-salt $C^6H^3P^2SO^4$, very soluble in water and in alcohol, and crystallising in needles when its aqueous solution is left to evaporate. The silver-salt is also crystallisable, very soluble in water and in alcohol, and blackens quickly when exposed to light. (Cahours.)

MESOLE. *Fürölit.*—A zeolitic mineral related to natrolite and scolecite, occurring in implanted globules with a flat-columnar radiate structure. Hardness = 3.5. Specific gravity = 2.35 to 2.4. Lustre silky or pearly. Colour greyish-white, yellowish, or reddish. Streak uncoloured. Translucent. Laminae slightly elastic.

Analysis.—a. From the Faröe Islands (Berzelius).—b. From Annakleif in Schonen (Hisinger).—c. From Bombay (Thomson):

	SiO^2 .	Al^2O^3 .	CaO .	Na^2O .	H^2O .	
a.	42.60	28.00	11.43	5.63	12.70	= 100.30
b.	42.17	27.00	9.00	10.19	11.79	= 100.15
c.	42.70	27.60	7.61	7.00	14.71	= 99.62

These results may be approximately represented by the formula $(2M^2O.8SiO^2).(2Al^2O^3.3SiO^2).6H^2O$, or for the Bombay mineral, $6H^2O$.

Harringtonite, a snow-white mineral, occurring in the amygdaloid of the north of Ireland, with a compact texture, and very tough, may be included in the same general formula. It contains, according to Thomson's analysis, 44.84 per cent. silica, 28.48 alumina, 10.68 lime, 5.66 soda, and 10.28 water (= 99.86).

MESOLITE. See SCOLECITE.

MESOTYPE. See NATROLITE and SCOLECITE.

MESOTARTARIC ACID. Syn. with INACTIVE TARTARIC ACID: see TARTARIC ACID.

MESOXALIC ACID. $C^3H^2O^4$ (Liebig and Wöhler, Ann. Ch. Pharm. xvi. 298.—Svanberg, Berz. Jahresh. xviii. 166.)—An acid formed when alloxan or alloxanic acid is boiled with aqueous alkalis, urea being simultaneously produced:

The acid is obtained by decomposing the barium-salt by sulphuric acid, or the lead-salt by sulphydric acid. It is crystallisable, and has a very sour taste, and a strong acid reaction. It is very soluble in water, and its solution is not decomposed by boiling. Its aqueous solution, when neutralised with ammonia, gives with salts of barium, strontium, and calcium, white precipitates, soluble in acids, or in a large quantity of water.

Mesoxalic acid is dibasic. The *barium-salt*, $C^3Ba^2O^5$, is prepared by boiling a hot saturated solution of alloxanate of barium: a mixture of alloxanate, mesoxalate, and carbonate is precipitated, and the solution yields, on evaporation, crystalline crusts of urea and mesoxalate of barium, the latter of which is removed by washing with alcohol. The salt forms yellow laminae, which are anhydrous at 90° , and at 100° are partially decomposed. Liebig and Wöhler found 55.93 per cent. barium in the salt; the calculated percentage is 56.49. The *calcium-salt* forms thin tables, which at 90° contain 2 at. water.; at 140° they lose 1 at. water, and above that temperature are decomposed. It is much more soluble than the barium-salt (Svanberg). The *lead-salt*, obtained by dropping aqueous alloxan or alloxanic acid into a boiling solution of neutral acetate of lead, appears to be a basic salt, containing 4 at. lead. It is decomposed when gently heated in the air, pure oxide of lead remaining; hot nitric acid converts it into oxalate of lead. According to Liebig and Wöhler, the normal lead-salt is formed by adding mesoxalic acid to neutral acetate of lead. The *silver-salt* is obtained as a yellow precipitate when mesoxalic acid and ammonia are added to nitrate of silver: it is probably a basic salt, as it is entirely decomposed by heat into carbonic anhydride and metallic silver, perhaps thus, $C^3Ag^2O^5 + Ag^2O = 3CO^2 + Ag^4$. (Liebig and Wöhler.)

When mesoxalic acid is compared with carbonic and oxalic acids, it will be seen that the three acids may be regarded as containing respectively the diatomic radicals carbonyl CO, oxalyl C^2O^2 , and mesoxalyl C^3O^3 .

Carbonic acid	$C^2H^2O^3 = CO.H^2O^2$.
Oxalic acid	$C^2H^2O^4 = C^2O^2.H^2O^2$.
Mesoxalic acid	$C^3H^2O^5 = C^3O^3.H^2O^2$.

The decomposition of oxaluric and alloxanic acids into urea, oxalic, and mesoxalic acids, respectively, shows that alloxanic bears to oxaluric acid the same relation that mesoxalic does to oxalic acid, and from this point of view alloxanic acid may be regarded as mesoxaluric acid. A similar relation is evident between alloxan and parabanic acid. F. T. C.

MESUA FERREA. This plant, which grows in India, yields a fixed oil having a density of 0.954, a chestnut-brown colour, and solidifying at +5. (Lepine, J. Pharm. [3] xl. 16.)

METACETAMIDE. Syn. with PROPIONAMIDE.

METACETIC ACID. Syn. with PROPIONIC ACID.

METACETONE. $C^3H^4O^2$? (Frémy, Ann. Ch. Phys. [2] lix. 6.—Gottlieb, Ann. Ch. Pharm. lii. 127.)—A substance occurring among the products of the dry distillation of sugar, starch, gum or mannite, with lime; it has also been obtained by the distillation of lactate of calcium, and occurs among the volatile oils formed by the distillation of wood.

Frémy prepares metacetone by gently heating an intimate mixture of at least 500 grms. of sugar with 8 times its weight of quicklime in a capacious retort, withdrawing the fire after a while, because the water disengaged from the sugar, coming in contact with the lime, raises the temperature high enough to complete the reaction without further application of external heat. If the mixture has been well made, scarcely any inflammable gas is evolved, and a complex oil passes over into the receiver. This oil is shaken up with water to remove the acetone which it contains, and the residue, which floats on water, is rectified till it exhibits a constant boiling point. It is difficult, however, to obtain a pure product. According to Gottlieb, it is best to use only 3 pts. lime to 1 pt. sugar, and to keep the receiver cool. Metacetone is obtained in the same manner from starch, which indeed appears to yield rather more metacetone than acetone: gum, on the contrary, yields a comparatively larger quantity of acetone.

Metacetone is a colourless oil, having an agreeable odour, insoluble in water, very soluble in alcohol and ether. Boiling point 84° . It contains, according to the mean of Frémy's analyses, 72.2 per cent. carbon, and 10.1 hydrogen. The formula $C^3H^4O^2$,

ch represents it as isomeric with oxide of mentyl and oxide of allyl, requires 73.5 per cent. hydrogen, and 16.3 oxygen. When distilled with *acid chromate of potassium* and strong *sulphuric acid*, it yields carbonic anhydride, acetic acid, and propionic acid. As these products are the same as those obtained by the oxidation of propione, acetone is sometimes regarded as impure propione (G. m. ix. 409). (Pure propione, $\text{C}_3\text{H}_6\text{O}$, obtained by distillation of propionate of barium, boils at 84° and contains 1 carbon, and 11.8 hydrogen.) Metacetone dropped on heated *potash-lime* or fused *rate of potassium* distils over in great part unaltered, the residue containing only a trace of propionic acid. (Gottlieb.)

METACETONIC ACID. Syn. with PROPIONIC ACID.

METACETONITRILE. Syn. with PROPIONITRILE or CYANIDE OF ETHYL (211).

METACHELORITE. A foliated columnar mineral from the Büchenberg near Angerode in the Harz. It has a vitreous to pearly lustre and dull leek-green colour. Density = 2.5. Gelatinises with acids. Contains, according to List, 23.77 per cent. silica, 16.43 alumina, 40.36 ferric oxide, 3.10 magnesia, 0.74 lime, 1.37 potash, 0.08 soda, and 13.75 water (= 99.60), whence the formula $3(\text{MgO} \cdot \text{SiO}_2) \cdot 2(\text{AlPO}_4 \cdot \text{SiO}_2) \cdot 10\text{H}_2\text{O} + (\text{MgO} \cdot \text{SiO}_2) \cdot (3\text{MgO} \cdot 2\text{AlPO}_4) \cdot 8\text{H}_2\text{O}$. (*Rammelsberg's Mineralchemie*, p. 541.)

METACHROMIC OXIDE. See CHROMIUM, OXIDES OF (i. 940).

METACINNAMEIN. See CINNAMEIN (i. 980).

METACROLEIN. See ACROLEIN (i. 57).

METAFERRIC OXIDE. The modification of ferric hydrate obtained by Péan St. Gilles by boiling the ordinary yellow hydrate in water (p. 395).

METAFURFUROL. See FURFUROL (ii. 752).

METAGALLIC ACID. See GALLIC ACID (ii. 760).

METAHUMIC ACID. See ULMIC ACID.

METAL. *Metall.* *Métal.* **METALLOID.** *Metalloid.* *Métalloïde.* The term *metal* has long been commonly applied, in technical and popular language, to a number of substances which agree in presenting, in various degrees, a combination of certain ill-defined physical characters, by which many of them are easily distinguishable from most other substances. Gold and silver were formerly regarded as the typical representatives of this class of substances. These characters, however, are not by any means absolutely distinctive of metals; for there are many substances which are not metallic, and which nevertheless possess in a high degree some of the physical characters of metals. At a very early date, attempts made by Basil Valentine (*Constitutiones*), Paracelsus (1539), and Boerhaave (1732), to adopt a system of classification, which would separate the more characteristic metals from substances possessing certain metallic characters, such as zinc, antimony, bismuth, antimony-glance, pyrites, and galena, which were termed *semi-metals* or *bastard metals*. In 1736, Lavoisier proposed to make the presence or absence of malleability the principle of this classification, and upon this ground he separated mercury from the metals. The same view was adopted by Vogel (1765, *Institutionibus Chemicæ*) and Buffon (1785, *histoire naturelle des Minéraux*). Subsequently, when Braune had observed the solidification of mercury by cold in 1759-60, and this had been confirmed by Hutchinson and Cavendish in 1783, the malleability of this substance became known, and it was classed among the metals.

The insufficiency of the distinction which had been drawn between metals and semi-metals was pointed out by Fourcroy (1789, *Éléments d'Histoire Naturelle et de Chimie*, 380) as being evident from the fact that "between the extreme malleability of gold and the singular fragility of arsenic, other metals presented only imperceptible gradations of this character, and because there was probably no greater difference between the malleability of gold and that of lead, which was considered to be a metal, than there was between lead and zinc, which was classed among semi-metals, while in the substances intermediate between zinc and arsenic the differences were slight." The distinction between metals and semi-metals was soon afterwards abandoned, and at the time when the existing system of chemistry was established by Lavoisier, the class *Metal* comprised seventeen substances. Their chemical relations were not a little known, and they were classified together as metals, chiefly on account of their analogy in physical characters, and because they were regarded as chemically simple or elementary substances. Since that time a great number of other simple substances have been discovered, which possess more or less the physical characters of metals, but which do not possess them in that degree which was formerly considered to be the distinctive peculiarity of a metal.

On the discovery of potassium and sodium by Davy in 1807, doubts were entertained as to their metallic nature, and it was proposed to distinguish them from metals on account of their peculiar physical characters, and to term them *metalloids*,* as possessing only some resemblance to metals (Erman and Simon, 1808, *Gilbert's Annalen*, xxviii. 121). This proposal was not adopted, and in 1811 Berzelius applied the term *metalloid* to distinguish the non-metallic elementary substances from the metals, in which sense it has been commonly used up to the present time, chiefly in relation to substances which, like the metals, have not been resolved into separate constituents, and which are consequently regarded as elementary.

A high degree of density was long considered to be a peculiarly distinctive character of metallic substances; but the discovery of the earthy and alkaline metals showed that this is not the case, and that, in regard to this, as well as other physical characters, the term metal has only a relative application, and should not be considered as representing a class of substances entirely distinct from those termed metalloids.

This fact has been rendered still more apparent by the advanced investigation of the chemical characters and relations of metals and other substances; for while some of the substances possessing, in a marked degree, certain of the physical characters, hitherto regarded as distinguishing metals, do not possess, in an equal degree, the chemical characters of metals, there are, on the contrary, substances possessing few or none of the physical characters of metals, but manifesting in their chemical characters and relations the most marked analogy with well-defined metals. Thus for instance antimony, molybdenum, arsenic, titanium, &c., form compounds with oxygen, sulphur, &c., which are the analogues of sulphuric, phosphoric, nitric, and silicic acids; while, on the other hand, the electropositive constituents of the earths and alkalis, also hydrogen, ammonium, and some of the hydrocarbon radicles, correspond closely with the electropositive metals, in their general chemical functions, and form with oxygen and sulphur, &c., compounds which are in the highest degree analogous to the basic compounds of silver, lead, iron, &c., with oxygen.

In a strictly chemical sense, therefore, the term metal must be regarded as representing an ideal type, to which a number of substances approximate more or less, independently of their physical characters and of their simple or compound nature.

The elementary substances generally regarded as metallic are mostly solid at the ordinary temperature, the only exception being mercury (p. 933). With the exception of arsenic, they are all capable of becoming liquid at various temperatures peculiar to each, and some of them are capable of being converted into vapour by heat. In the solid and compact state they are in a high degree impervious to light. A mass of metal is absolutely opaque; but very thin laminae of some metals allow certain rays to penetrate through them, as for instance gold-leaf, which transmits light of a green colour. (Faraday, see pp. 636, 642.)

In consequence of this impermeability by light and the accompanying high refractive power of metals in the compact or liquid states, they possess a peculiar lustre or brilliancy, which may be developed by polishing their surfaces. The colour of most metals is a peculiar grey, with a varying tint of blue; but some few are yellow, such as gold and copper, brass, bronze, &c. (see LIGHT, p. 641 *et seq.*), the colour being due to an unequal power of absorption for different rays, and varying according to the angle which the incident rays form with the surface of the metal. When this angle is very small, the whole of the rays are reflected, and all metals appear quite colourless.

One of the characters which, in combination with those already mentioned, has been regarded as most distinctive of metallic substances, is an internal mobility, in virtue of which the shape of a mass of metal may be altered by pressure, hammering, or by other mechanical means, without disintegration or disruption of the mass. This character, which is presented in various degrees and modes by different metals, is expressed by the terms *malleability*—denoting the capability of flattening or spreading out under the hammer, or between rollers—and *ductility*—denoting the capability of becoming longer and thinner by drawing through a hole of less area than the transverse section of the piece of metal.

For individual metallic substances, the degrees of malleability and ductility are by no means equal; many metals, which are in a high degree malleable, as tin and lead, cannot be drawn into very fine wire, while others which are less malleable, as iron, copper, gold, possess far greater ductility. Both characters are considerably influenced by temperature. Within certain limits they are generally greater at high than at low temperatures. The mechanical working of a metal is also productive of an alteration in its molecular condition, attended with diminution of malleability and ductility (*hammer-hardened*; *écroué*). In such cases those characters may be restored to the metal by heating it and allowing it to cool slowly (*annealing*; *anlassen*; *recuire*).

* From *μέταλλον*, metal and *οἶδος*, likeness.

Metals possess so little malleability or ductility that they cannot be rolled into wire.

Brittleness, or the resistance to forces which tend to tear asunder, either by tension, or by bending, or wrenching, is another character which metals possess in very unequal degrees. It is intimately connected with molecular condition, and is in some way related to malleability and ductility. It is largely influenced in particular metals by the presence or absence of certain admixtures; by the manner in which they have been worked into shape, and by temperature. In general it is reduced by increase of temperature; but in some cases it is increased within a certain limited range of temperature, as in the case of iron (see COHESION, i. 1078). Some metals possess but a very slight degree of tenacity, and are then termed brittle—as zinc, antimony, and arsenic.

Elasticity, or the capability of a bar of metal to recover its original shape and dimensions, after being bent or stretched, is also a character connected with tenacity and internal mobility. It varies much in different metals.

Metallic substances differ very widely in the degree of *hardness* they possess, or are capable of acquiring by sudden cooling or otherwise. Some are so soft as to admit of being kneaded like wax (potassium and sodium), others are capable of scratching quartz or even diamond (steel, chromium). The presence of small amounts of various substances, such as carbon, silicon, &c., in metals, often communicates to them considerable hardness. As a general rule, a metal is more brittle in proportion to its degree of hardness.

Metals are capable of assuming a *crystalline structure*, generally belonging to the cube, octahedron, or some other form of the regular system; antimony and arsenic crystallise in rhombohedrons. Metals occurring native are frequently crystallised. The existence of crystalline structure in a metal, considerably influences its tenacity. It is generally accompanied by an increased degree of brittleness, and those metals which are most easily crystallised are, as a general rule, the most brittle. Crystalline structure is sometimes assumed by metals, while in the solid state, under the influence of long continued heat, or percussion or of vibration, and other mechanical actions, and the change thus induced is often of importance in relation to technical applications (see *Iron, &c.*, p. 327). Metals may often be crystallised by slowly cooling them in a molten state, and when partly solidified, pouring off the remaining liquid metal (see *DESPRETZ*, i. 590; *LEAD*, iii. 478). Metals often assume a crystalline structure when deposited from solutions of their saline compounds, and some can be crystallised by *evaporation* (zinc, arsenic).

Metals and metalloids in general present a marked difference in their power of conducting electricity and heat: the conductivity of metals for electricity is greater than that of any other substances. It varies considerably in different metals, and to some extent in the individual metals, according to their molecular condition, temperature, and the presence or absence of foreign admixtures.* The purer and softer the metal, the greater its conductivity: the higher the temperature of the metal, the less its conductivity. The conductivity of some metalloids is increased by elevation of temperature. (See *Wiedemann, Lehre vom Galvanismus und Electromagnetismus*, i. 180.—*Matthiessen*, 1856, *Proc. Roy. Soc.* xi. 516.)

Metals and metalloids differ in their electrical relations, the former being, as a class, electro-positive, the latter electro-negative. The distinction, however, is only one of degree, and metals present similar differences among each other. (See *ELECTRICITY*, p. 432.)

Metals differ widely in their capacity for heat. The specific heat of sodium amounts to nearly ten-fold that of bismuth, lead, mercury, or gold. The conductivity for heat also differs greatly, though metals generally possess a comparatively high degree of conductivity for heat. (See *Despretz*, *Compt. rend.* xxxv. 540.—*Wiedemann* and *Franz*, 1854, *Ann. Ch. Phys.* xli. 107.)

The following table presents some of the principal physical characters of the most known elementary metals and metalloids, so far as they have been determined. In some cases the numbers given are only approximative. It must also be remembered that the existence of these characters, and the degrees in which they are manifested by particular substances, are sometimes due to the molecular condition of the substance, rather than to any inherent peculiarity. This is more especially known to be the case with the metalloids, several of which are polymorphic, as sulphur, phosphorus, boron, silicon, &c. (See *DIMORPHISM*, ii. 331.)

* The values given in the accompanying table are taken from *Matthiessen's* experiments (*Phil. Mag.* 1856, p. 122, *Phil. Mag.* (4) xli. 81). The letters A, P, and S prefixed to the numbers in columns 1, 2, and 3, signify that the wires were *hard-drawn*, *pressed*, or *soft*.

Only a few metals occur native, viz. gold, platinum, palladium, iridium, and rhodium, which are almost always found in the metallic state—silver, copper, mercury, bismuth, arsenic, which are often found in the metallic state—iron, antimony, lead? zinc? which are very rarely found in that state.

For the most part, metals occur naturally as constituents of various minerals, in which they are combined with oxygen, sulphur, chlorine, or arsenic, &c., in various proportions and modes.

Of the metalloids only three occur native to any considerable extent, viz. nitrogen, oxygen, and sulphur. Carbon and selenium occur but rarely in an isolated state. It is doubtful whether fluorine has yet been obtained in the free state, even artificially (see ii. 673).

In the chemical characters and relations of metals and of metalloids, there are differences as great as in their physical characters. These differences, however, are manifested more in the functions which the substances of one or other class perform, in their compounds with other substances, than by the capability of direct combination with each other, which is considerably influenced by various physical conditions, such as temperature, state of aggregation, &c.; hence also this mode of chemical action should probably be regarded merely as a phase of some more general dynamic property, rather than as the exercise of a peculiar force, inherent in the different elementary substances. (See CHEMICAL AFFINITY, i. 850 *et seq.*) But in any case, the existence of chemical compounds, and their characters in relation to other substances, must be regarded as results of the same mutual activity which determines chemical combination. Probably all elementary substances are more or less capable of existing in a state of chemical combination with each other; but those possessing this capability in the highest degree are, as a rule, either the most opposite in their general chemical relations, or else capable of assuming special functions in relation to certain others. The elementary substances possessing the most universal capability of existing in combination with others, and of direct combination, are fluorine? oxygen, sulphur, chlorine, bromine, iodine, and some of the metals.

Hydrogen and oxygen, which present the most decided differences in their general chemical relations, may be taken as typical of the two classes of elementary substances—metals and metalloids—the one representing the basylous, and the other the chlorous constituents of compounds. (Graham.)

The basylous or chlorous characters of the elementary substances are not however absolute, except perhaps in the case of fluorine and oxygen. On the contrary, they vary according to the kind of substances existing in combination. Thus, for instance, chlorine and sulphur are both basylous in relation to oxygen, but chlorous in relation to hydrogen and most other elementary substances; again, among the metals which are generally basylous in their relations to other substances, some are capable of existing in combination with others, in relation to which they are then feebly chlorous.

In compound substances consisting of two elementary radicles, their chemical characters and relations to each other generally approximate to the basylous or chlorous condition more or less in proportion to the relative preponderance of one or other of those characters in one of the constituents. Thus, for example, in water the relatively basylous and chlorous characters of hydrogen and oxygen are so nearly balanced that it is almost destitute of any chemical activity as an independent substance, and that which it does exhibit is, according to circumstances, sometimes basylous, as in hydric sulphate, nitrate, &c., and sometimes chlorous, as in potassium-hydrate, calcium-hydrate, &c.

In hydrochloric acid, however, the chlorous character of chlorine relatively to hydrogen exceeds that of oxygen, in such a degree that this substance is decidedly chlorous in relation to those substances with which it can exist in combination. But in hypochlorous acid, though chlorine is basylous relatively to oxygen, that substance is feebly chlorous in its compounds. In soda and sodium-chloride, on the contrary, the basylous character of sodium exceeds that of hydrogen, relatively to oxygen and chlorine, in such a degree that the former is highly basylous, and the latter slightly so.

The chemical activity of compounds as independent substances, is not by any means proportionate to that of their constituents; thus, for instance, nitrogen is one of the most indifferent substances, but its compound with hydrogen is a powerful alkali, and some of its compounds with oxygen are powerful acids.

The proportion in which two elementary substances are combined also influences the chemical characters and relations of the compound. Thus, in sodium-peroxide, containing twice as much oxygen as soda does in proportion to sodium, the basylous character disappears, and this compound is destitute of any chemical activity as an independent substance. Again, manganous oxide is highly basylous, and manganic oxide slightly so, while the peroxide is indifferent, and the higher oxides are chlorous. In like manner the compounds of nitrogen and of chlorine, bromine, iodine, &c. with oxygen, are more decidedly chlorous in proportion to the amount of oxygen they contain.

The chemical function of manganese in manganous oxide is essentially different from that which it exercises in manganic or permanganic acids. In the former case the metal corresponds with, and is chemically equivalent to, hydrogen in water; in the latter case it corresponds with, and is equivalent to, chlorine and nitrogen in chlorous and nitrous acids, and to chlorine in perchloric acid. (See CLASSIFICATION, i. 1007; and EQUIVALENTS, ii. 491.)

Certain compounds of elementary substances present, in their general chemical relations and functions, a very close analogy with the metals and metalloids; as, for instance, cyanogen (see ii. 275) and the hydrocarbon radicles. (See RADICLES.)

Compounds are usually named generically according to their chlorous constituents, and specifically according to their basylous constituents; thus compounds in which oxygen, sulphur, or chlorine, &c., are the chlorous constituents are termed *oxides, sulphides, chlorides*, &c. (see NOMENCLATURE). In the case of compounds in which the relative basylous and chlorous functions of the constituents are less marked or not easily determinable, names of a more arbitrary nature are commonly used; thus, for instance, the compounds of metals with each other are termed *alloys*, and those alloys in which one of the constituents is mercury are termed *amalgams*.

Since the specific descriptions of particular compounds will be found under their respective heads, it does not come within the scope of the present article to do more than point out the leading characteristic features of the most important classes of compounds, viz. oxides, sulphides, &c.

Oxides. All the elementary substances, except fluorine, are capable of existing in combination with oxygen, in one or several proportions.

The physical characters of oxides are generally very different from those of their constituent basylous radicles. Among the metalloidal oxides, some are gaseous under ordinary conditions, as carbonic oxide, carbonic acid,* some of the nitrogen oxides, sulphurous acid, &c.; some are liquid, as nitrous acid; others are solid, as nitric acid, sulphuric acid, silica, &c. Among the metallic oxides, all of which are solid, some are volatilisable, as arsenious acid, antimonious oxide; the others are fixed and mostly infusible and insoluble in water. Formerly metallic oxides were called *calces*, and their production was termed calcination. (See GAS, ii. 774.)

Many oxides occur native in great abundance; thus among those of the metalloids, carbonic acid is a constituent of the atmosphere and of a great number of mineral substances. Silica also is very abundant both in the states of quartz, flint, sand, &c., and as a constituent of numerous minerals and rocks. Sulphuric acid occurs frequently as a constituent of various minerals, as gypsum, selenite, heavy spar, &c.; boric acid occurs in the lagoons of Italy, and in some minerals: phosphoric acid is very widely distributed throughout the mineral kingdom, in small relative quantity, and it occurs abundantly in plants and animals. Among the metallic oxides, water, the earths, and the alkalis are probably the most abundant; existing as constituents of various minerals and rocks. Among the compounds of the heavy metals with oxygen, the oxides of iron, manganese, and zinc are the most abundant, either as such or in combination with carbonic acid, silica, &c.

The chemical relations of the oxides are as diverse as those of elementary substances. Among the metalloidal oxides containing the smallest proportions of oxygen, some are characterised by their chemical indifference, as individual substances, in relation to most other substances, as for instance carbonic oxide, nitrous oxide, &c. Those containing larger proportions of oxygen are possessed of considerable chemical activity; and, in their compounds with other oxides, they present relations which are generally of a more or less decidedly chlorous character, as for instance sulphuric, nitric, and carbonic acids.

The metallic oxides containing the smallest proportions of oxygen are sometimes characterised by their chemical indifference, as for instance suboxide of lead; but they more generally present relations of a basylous nature in their compounds with other oxides, as for instance potash, soda, zinc-oxide, silver-oxide, &c. Among those containing larger proportions of oxygen, some, such as ferric oxide, alumina, &c., present this character in a less marked degree, and in some of their compounds they are chlorous, as in potash-aluminate, &c. Other metallic oxides containing still larger proportions of oxygen, such as manganese-peroxide, &c., are mostly indifferent as individual substances; but the oxides containing the largest proportions of oxygen are in many cases decidedly chlorous in their compounds with other oxides; as for instance, manganic acid, permanganic acid, stannic acid, chromic acid, &c.

The chemical relations of compounds consisting of two different oxides are generally of a nature corresponding to those of hydrochloric acid and potassium-chloride to other chlorides, and the mutual relations of their constituents correspond with those of

* The word "acid" in this article is used in the sense of *anhydrous acid* or *anhydride*, e.g., carbonic acid CO₂; nitric acid N²O₅, &c.

hydrogen and chlorine in hydrochloric acid. (See SALTS; and ACIDS, i. 39; ALKALI, i. 115; BASE, i. 519.)

Many oxides containing the largest proportions of oxygen are decomposed at various temperatures by the action of heat alone, yielding oxygen-gas and lower oxides. Excepting nitric acid, which is readily decomposed by heat, most of the other higher oxides of the metalloids which are known in a separate state, are capable of supporting high degrees of temperature without decomposition. The sesquioxides and peroxides of metals are generally decomposed by heat into oxygen and lower oxides, and all the oxides of silver, gold, platinum, &c., are decomposed by moderate degrees of heat into oxygen-gas and the respective metals. Some oxides, on the contrary, combine with a further quantity of oxygen, either at the ordinary temperature, as for instance manganous and ferrous oxides, or when heated in contact with oxygen or atmospheric air, as plumbous oxide. This change takes place most readily in some cases when the oxide is in combination with water, or when water is present.

Most oxides may be decomposed to a greater or less extent by the simultaneous action of heat and of some other substance capable of combining with oxygen, and of abstracting it from the oxide operated upon, so as to form an oxide of greater stability under the circumstances. This reduction, as it is termed, is complete when the whole of the oxygen is separated from the basylous radicle, and partial when there is only a lower oxide produced. The most powerful reducing agents are the alkali-metals, hydrogen, carbonic oxide, and carbon. Even carbonic oxide is decomposed by potassium or sodium with the aid of heat. The oxides of the metalloids are mostly susceptible of reduction by carbon with the aid of heat. Among metallic oxides those of iron, copper, lead, bismuth, &c., are completely reduced by hydrogen at a red heat; the oxides of manganese and uranium, &c., are but partially reduced; oxide of zinc with difficulty; while the lower oxides of chromium, manganese and uranium, and the oxides of the earthy and alkali-metals are not affected by hydrogen. In the reduction of metallic oxides by means of carbonic oxide or carbon, the metal eliminated often contains carbon in a state of combination with it. At very high temperatures, carbon reduces some oxides which are not affected by hydrogen, as for instance soda and potash at a white heat.

When the reduction of a metallic oxide by carbon is effected at a comparatively low temperature, carbonic acid is formed; but when it takes place only at a very high temperature, carbonic oxide is produced.

The reduction of metallic oxides may also be effected by heating them with metals whose oxides are less readily reduced. Thus potassium reduces several metallic oxides, and among others ferric oxide at a red heat; but at a white heat, potash is decomposed by iron. The result in this latter case may be due to the volatility of potassium at that temperature, and the consequent removal of small portions reduced under the influence of a preponderating mass of iron, so that this action takes place repeatedly until the whole of the potash is decomposed, and without any possibility of action between the potassium and oxide of iron.

By the action of heat and reducing agents upon compound oxides, such as sulphates, phosphates, &c., there may be produced a compound of the metal with the chlorous radicle, as sodium-sulphide, by heating to reduce a mixture of the corresponding sulphate with carbon. If the radicle of the chlorous constituent of the compound does not combine with the metal under the circumstances, it may be volatilised in the state of a lower oxide, as in the reduction of nitrates.

Some compound oxides, such as carbonates, nitrates, &c., are decomposed by the mere action of heat, the acid being eliminated either unaltered or decomposed, and the metallic oxide remaining either in the same state as it existed in the original compound or in a higher state of oxidation; thus ferrous carbonate yields by ignition, ferroso-ferric oxide and a mixture of carbonic oxide with carbonic acid.

Certain metals and metalloids do not, under any known circumstances, combine directly with oxygen; for example, gold, platinum, nitrogen, chlorine, bromine, iodine, &c. All the others are capable of combining directly with oxygen, some of them at very low temperatures, as for instance sodium, potassium, &c.; others like copper, iron, carbon, sulphur, phosphorus, &c., when heated to temperatures differing for each. In all cases the direct combination with oxygen is attended with evolution of heat, and if it takes place rapidly, it is also attended with evolution of light. (See COMBUSTION, i. 1089.)

The physical condition of substances capable of combining directly with oxygen, influences very much the facility with which the combination takes place. A state of minute subdivision is most favourable, while a compact condition is most opposed to combination, especially when the resulting oxide is infusible at the temperature produced by the combination, and forms a protecting crust over the surface of the substance. Thus pulverulent copper, heated to about 450°C ., takes fire in oxygen gas.

and is completely converted into oxide; but a plate of copper under the same conditions merely becomes covered with a crust of oxide. On the contrary, a red-hot iron wire continues to burn in oxygen gas, because the resulting oxide is melted at the temperature produced, and thus a fresh metallic surface is exposed to the action of the gas.

The indirect oxidation of metals and metalloids may be effected by heating them with substances which evolve oxygen when heated, such as nitrates, chlorates, &c. Some metals, such as iron, zinc, &c., decompose water in the presence of acids, and form oxides which combine with the acid. Others decompose water alone at the ordinary temperature, like sodium, or by the aid of heat, like aluminium, magnesium, iron, &c. Others again decompose water in the presence of an alkali, and with the aid of heat, like aluminium and zinc. The behaviour of iron with water-vapour, and that of ferric oxide with hydrogen, present a striking illustration of the influence of circumstances on the exercise of chemical affinity. The production of ferric oxide in the one case, and the reduction of the same substance in the other, are most probably due to the respective preponderance of water-vapour relatively to hydrogen, and of hydrogen relatively to water-vapour, and also to the constant removal of the hydrogen and the water-vapour which are produced in the two cases by the action taking place. A similar influence is also manifested in the reduction of zinc-oxide by hydrogen. (Dewille.)

The facility with which different metals combine with atmospheric oxygen under ordinary circumstances, varies very much. While the alkali-metals are rapidly oxidised even in dry air, neither gold, silver, nor platinum is at all affected in any case. Some metals, such as iron, however, which remain perfectly bright in dry air or even oxygen, rapidly become oxidised in moist air, and covered with a coating of oxide. The presence of acid vapours in the atmosphere facilitates this action upon most oxidisable metals, but in the case of some it does not extend beyond the surface. Thus, for instance, zinc, when superficially oxidised by exposure to the atmosphere, does not undergo further oxidation, the portions underlying the crust of oxide being in fact protected by it. In the case of iron, on the contrary, the oxidation progresses until the whole of the metal is converted into oxide, or as it is termed rust, and it even proceeds with accelerated rapidity after the first oxidation of the surface has taken place: for the electropositive relation of the iron to oxygen is augmented by its contact with the ferric oxide, and its combination with oxygen is thereby facilitated so much that the metal is capable of decomposing water.

A different application of the same principle may be made the means of preventing the oxidation of iron. Thus if the metal is placed in contact with a substance which renders iron electronegative in relation to it, the affinity of iron for oxygen is reduced, and it becomes less liable to oxidation than it would otherwise have been. This fact has been practically applied in the galvanising of iron, which consists in coating iron with a thin layer of zinc which becomes electropositive in relation to iron, and though the zinc is thus rendered more liable to oxidation, it still protects the iron, since the oxidation of the zinc is only superficial, and the production of a thin film of oxide upon it prevents further action.

Sulphides. These form a very numerous class of substances, which, consistently with the chemical analogy between sulphur and oxygen, present in their general relations considerable similarity to the oxides. They contain various proportions of sulphur, and are accordingly termed *proto-, sesqui-, di-, tri- and penta-*sulphides. With the exception of carbon-disulphide, which corresponds to carbonic acid, the sulphides of the metalloids are but little known: there appear to be several sulphides of phosphorus, and probably more than one sulphide of nitrogen. (Faraday, Quart. Journ. Sci. iv.; Soubeiran, Ann. Ch. Phys. [2] lxvii. lxxi.)

The sulphides are capable of forming compounds with each other—sulpho-salts—analogous to the compounds of oxides, in which the sulphides of the most basylous elementary radicles, and those containing the smallest proportions of sulphur—the sulpho-bases—are basylous in relation to sulphides containing larger proportions of sulphur and less basylous radicles—sulpho-acids. Thus potassium-sulphide combines with carbon-disulphide and with arsenic-pentasulphide, forming potassium-sulpho-carbonate and potassium-sulpho-arsenate. The sulphides of the alkali-metals were formerly called liver of sulphur.

Many sulphides combine with water and some other oxides, as well as with chlorides and iodides, &c.

The physical characters of some metallic sulphides closely resemble those of the metals in certain particulars, such as the peculiar opacity, lustre, and density, especially when they are in a crystalline condition. They are generally crystallisable, brittle, and of a grey, pale yellow, or dark brown colour. The sulphides of the alkali-metals are soluble in water, most of the others are insoluble. They are more frequently fusible

than the corresponding oxides, and some are volatilisable, as mercury-sulphide, arsenio-sulphide. Carbon-disulphide is an oily liquid, insoluble in water.

Metallic sulphides occur native in great abundance in the various forms of pyrites, blende, and glance. They are the principal sources from which certain metals, such as lead, copper, &c., are extracted.

Many sulphides, when heated out of contact with atmospheric air, do not undergo any decomposition; this is the case chiefly with those containing the smallest proportions of sulphur, such as the protosulphides of iron and zinc. Sulphides containing larger proportions of sulphur are partially decomposed by heat, losing part of their sulphur, and being converted into lower sulphides, or partially reduced, as in the case of iron disulphide. The sulphides of gold and platinum are completely reduced by heat.

Some sulphides may be decomposed by the simultaneous action of heat and of substances capable of combining with sulphur. Thus, for instance, silver, copper, bismuth, tin, and antimony sulphides are reduced by hydrogen; copper, lead, mercury, and antimony sulphides are reduced by heating with iron; but, in this case, some of the sulphide escapes decomposition, and combines with the iron-sulphide produced, forming a sulpho-salt.

Sulphides which are not reduced by heat alone, are always decomposed when heated in contact with oxygen or atmospheric air. Those of the alkali- and earth-metals are converted into sulphates by this means. Zinc, iron, manganese, copper, lead, and bismuth sulphides are converted into oxides, and sulphurous acid is produced; but when the temperature is not above dull redness, some sulphate is formed by direct oxidation. Mercury and silver sulphides are completely reduced to the metallic state. Some native sulphides gradually undergo alteration by mere exposure to the atmosphere, but it is then generally limited to the production of sulphates, unless the oxidation takes place so rapidly that the heat generated is sufficient to decompose the sulphate first produced. In the production of some metals for use in the arts, the separation of sulphur from the native minerals is effected chiefly by means of this action in the operations of roasting. (See METALLURGY.)

Some metallic sulphides are also decomposed by heating them in contact with water-vapour, with production of metallic oxides and sulphuretted hydrogen: lead, antimony, and mercury sulphides are but partially or little affected, and the sulphides of alkali- or earth-metals are converted into sulphates, hydrogen being eliminated.

Metallic sulphides are decomposed in like manner when heated with metallic oxides in suitable proportions, yielding sulphurous acid and the metal of both the sulphide and oxide. Metallic sulphates and nitrates exercise a similar action, yielding various proportions of metallic oxide and basic sulphates according to the proportions of the substances reacting.

Many metallic sulphides are decomposed by acids in the presence of water, sulphuretted hydrogen being evolved, while the metal enters into combination with the acid or the chlorous radicle of the acid. Nitric acid when concentrated decomposes most sulphides, with formation of metallic oxide, sulphuric acid, sulphur, and a lower oxide of nitrogen. Nitromuriatic acid acts still more energetically in a similar manner.

Most of the metals and metalloids are capable of combining directly with sulphur when heated with it under suitable conditions. Gold and zinc do not combine directly with sulphur. The combination of metals with sulphur is attended with great evolution of heat, and also of light when it takes place rapidly, being in fact a true case of combustion in which sulphur takes the part of oxygen.

Sulphides are also produced by the action of metals upon sulphydric acid, both slowly at the ordinary temperature, and more rapidly by the aid of heat. Metallic oxides heated with excess of sulphur yield sulphurous acid and sulphides; sometimes a compound of sulphide and oxide, as in the case of manganese. The alkalis and earths do not yield sulphurous acid in this way, but hyposulphurous or sulphuric acid, which remains in combination with a portion of the base—liver of sulphur. Metallic sulphates heated with carbon are reduced, carbonic acid or carbonic oxide and sulphides being produced. Hydrogen gas exercises the same reducing action with production of water. Metallic oxides heated in contact with sulphuretted hydrogen or vapour of carbon-disulphide are converted into sulphides, with simultaneous production of water and carbonic acid or carbonic oxide according to circumstances.

Solutions of metallic compounds yield precipitates of metallic sulphides when mixed with solution of sulphydric acid, or of soluble sulphides. In the case of metals whose sulphides are decomposed by dilute acids, the sulphides are not precipitated unless there is an alkali added to neutralise the acid of the metallic salt.

Metallic sulphides are also produced by the reduction of sulphates by organic substances. Many native sulphides have no doubt been formed in this way.

Phosphides.—These compounds are but little known in a definite state; but they appear to be in general analogous to the sulphides in their chemical characters. The metallic phosphides are mostly brittle and fusible, and the presence of phosphorus in

metals renders them hard and brittle. (See COPPER, ii. 73; IRON, iii. 327, 334, 399, LEAD, iii. 557.)

The phosphides of the alkali- and earth-metals are decomposed by contact with water, yielding oxides and phosphoretted hydrogen. Some of the phosphides are converted by ignition in contact with air into basic phosphates, part of the phosphorus being volatilised.

Metallic phosphides may be produced, either by heating the metals with phosphorus, by the reduction of phosphates with carbon or hydrogen gas, or by the action of phosphoretted hydrogen upon solutions of metallic compounds. Some metals cannot be combined with phosphorus by any of these methods.

Chlorides.—All the elementary radicles, excepting fluorine, are known to be capable of existing in combination with chlorine. The compounds of chlorine with the metals generally correspond to the oxides. (See METALLIC CHLORIDES, i. 894 *et seq.*)

Among the chlorides of the metalloids, some correspond in their composition with the respective oxides, sulphides, &c. (See i. 899, 764, iii. 293.)

Bromides.—(See i. 672 *et seq.*)

Iodides.—(See iii. 284.)

Fluorides.—(See ii. 670 *et seq.*)

Nitrides.—With the exception of the nitride of carbon (see CYANOGEN, ii. 275), these compounds are but little known. The titanium-nitrides are among the most remarkable. Several other metals and metalloids appear to form definite compounds with nitrogen in several proportions. (See CARBAZOTE, i. 757; BORON, NITRIDE OF, i. 635; COPPER, ii. 67; IRON, iii. 391; MAGNESIUM, iii. 754; also NITROGEN.)

Carbides.—Several metals appear to be capable of forming compounds with carbon, but their chemical history is little known. The most important are the iron-carbides (iii. 371 and 329; also COPPER, ii. 52). Manganese probably forms compounds with carbon analogous to the iron carbides.

Silicides.—The compounds of silicium with the metals are still less known than the carbides. (See IRON, iii. 334, and MANGANESE, iii. 816.)

Alloys.—Most metals are probably, to some extent, capable of existing in a state of combination with each other in definite proportions; but it is difficult to obtain these compounds in a separate condition, since they dissolve in all proportions in the melted metals, and do not generally differ so widely, in their melting or solidifying points, from the metals they may be mixed with, as to be separated by crystallisation in a definite condition. Exceptions to this are met with in the cooling of argentiferous lead (iii. 504 *et seq.*), the crystallisation of brass (see COPPER, ii. 48), and of gun metal (ii. 44).

Some metals cannot be made to mix or combine with each other when melted together, except in very unequal proportions. Thus lead retains only 1·6 per cent. zinc, and zinc only 1·2 per cent. lead (see MATTHIËSEN and v. BOSE, 1861, Proc. Roy. Soc.). Even when metals are miscible in all proportions, it is difficult to say whether there is actual chemical combination, as in the case of potassium and sodium, tin and antimony.

The chemical force capable of being exerted between different metals may, as a rule be expected to be very feeble, and the consequent state of combination would therefore be very easily disturbed by the influence of other forces. The stability of such metallic compounds is however greater in proportion to the general chemical dissimilarity of the metals they contain. But in all cases of combination between metals, the alteration of physical characters, which is the distinctive feature of chemical combination, does not take place to any great extent. The most unquestionable compounds of metals are still metallic in their general physical characters, and there is no such transmutation of the individuality of their constituents as takes place in the combination of a metal with oxygen, or sulphur, or chlorine, &c. The alteration of characters in alloys is generally limited to the colour, degree of hardness, tenacity, &c., and it is only when the constituent metals are capable of assuming opposite chemical relations, that these compounds are distinguished by great brittleness.

The formation of actual chemical compounds is indicated in some cases, when two metals are melted together, by several phenomena, viz. the evolution of heat, as in the case of platinum and tin, copper and zinc, &c. The density of alloys, also differs from that of mere mixtures of the metals. In the solidification of alloys the temperature does not always fall uniformly, but often remains stationary at particular degrees, which may be regarded as the solidifying points of the compounds then crystallising. Tin and lead melted together in any proportions always form a compound which solidifies at 187° C. The melting point of an alloy is often very different from the point of solidification, and it is generally lower than the mean melting point of the constituent metals.

But though metals may combine when melted together, it is doubtful whether they

remain combined after the solidification of the mass, and the wide differences between the melting and solidifying points of certain alloys appear to indicate that the existence of these compounds is limited to a certain range of temperature. Matthiessen (Brit. Ass. Reports, 1863, p. 37) regards it as probable that the condition of an alloy of two metals in the liquid state may be either that of—

1. A solution of one metal in another; 2. Chemical combination; 3. Mechanical mixture; or, 4. A solution or mixture of two or all of the above; and that similar differences may obtain as to its condition in the solid state. He considers that the conductivity for heat and electricity are among the characters best calculated to indicate the chemical nature of alloys. In respect to electric conductivity, he divides metals into two classes, viz.:

A. Metals which, when alloyed with each other, conduct electricity in the ratios of their relative volumes—lead, tin, zinc, cadmium.

B. Metals which, when alloyed with each other, or with a metal of class A, do not conduct electricity in the ratios of their relative volumes, but always in a lower degree than that calculated from the mean of their volumes—bismuth, antimony, platinum, palladium, iron, aluminium, gold, copper, silver, &c.

The curves representing the conductivity of different series of alloys have the relation shown in the accompanying diagrams.

Group I. Those belonging to the alloys of metals in class A are almost straight lines. That of the lead-tin alloys is given as the type.

Group II. The curves of alloys of metals in class B show a rapid decrement on both sides of the curve, the turning points being connected together by nearly straight lines. That of the gold-silver alloys is given as the type.

Group III. The curves of alloys of metals in class A with those in class B show a rapid decrement on the side beginning with the metal belonging to class B, then turning and going in a

straight line to the other side, beginning with the metal belonging to class A. That of the tin-copper alloys is given as the type.

In regard to the alloys of the first group, if they were mechanical mixtures, the metals composing them, unless their specific gravities were the same, would separate into two layers when melted and slowly cooled, as in the case of the lead-zinc alloys (Matthiessen and v. Bose, Proc. Roy. xi. 430). But the alloys of lead and tin, for example, do not separate in the same way as lead and zinc. Moreover, homogeneous wires could not be obtained by pressing if these alloys were mechanical mixtures; but wires of the same alloy have been proved to have the same conducting power, whether taken from the press at the beginning or the end of the operation.

On the other hand, the agreement between the theoretic and actual conductivity of these alloys, as well as between the calculated and actual percentage decrement in conductivity between 0° and 100° C., indicates that, in the solid state, they are not chemical compounds. In regard to these particulars, the following law has been found to obtain for all alloys of the first and second groups, as well as for some of those belonging to the third group:

The actual percentage decrement in conductivity between 0° and 100° C. is to the calculated decrement, as the actual is to the calculated conductivity. (Matthiessen and Vogt, Proc. Roy. Soc. xii. 652.)

Among the alloys of the second group, some may be regarded as mechanical mixtures. Silver and copper fused and well stirred together, separate when slowly cooled, so that the mass contains different amounts of the metals at different parts (Levol, Journ. Pharm. xvii. 111). But these alloys are exceptional, and most of the alloys of this group may be regarded as solidified solutions of allotropic modifications of the metals in each other. The curves representing the conductivity of the different series of these alloys all have the typical form; and the decrement in conductivity between 0° and 100° C. agrees with the theoretical amount.

In the third group of alloys, the rapid decrement in the conductivity of those alloys of the several series which contain but very small amounts of a metal belonging to class A, cannot be ascribed to the existence of chemical compounds of the metals. For, in the first place, the amount of one of the metals in the alloys corresponding to the turning-points of the curves representing the conductivity of the series is too small, as will be seen by the following instances:

<i>Alloy.</i>	<i>Percentage.</i>
Bismuth-tin.	tin . . . 0.6
Bismuth-lead.	lead . . 2.0
Silver.	tin . . . 2.6

Again, the great similarity of the curves representing the conductivity of series of alloys belonging to this group, is opposed to the existence of chemical compounds in the solid alloys.

Moreover, the relation between the amount of different metals belonging to class A, and the decrement in conductivity of the alloys, is equally opposed to such a view of their condition. Thus in silver-lead and silver-tin alloys, the decrements in conductivity corresponding to 0.9 per cent. lead and 0.7 per cent. tin by volume are equal, and in bismuth-lead and bismuth-tin alloys, the decrements corresponding to 0.4 per cent. vol. lead and 0.62 per cent. vol. tin are equal. (See Matthiessen, Phil. Trans. 1860, p. 171.)

The influence exercised upon the conductivity of metals by the presence of small quantities of other metals does not appear to be in any way determined by the alteration of crystalline form or tendency to crystallise which are known to be influenced by that circumstance. (See Matthiessen and Vogt, Phil. Mag. 1862.)

If it be assumed that the metals belonging to class B undergo a molecular change when alloyed with one another or with metals belonging to class A, and that in each an allotropic condition is induced by a small amount of other metals, varying according to the different metals, then many of the phenomena characteristic of alloys may be explained. Thus, for instance, the curve representing the conductivity of zinc-copper alloys has the same form as those of other alloys belonging to the same group, and the percentage decrement in their conductivity between 0° and 100° C. is exactly what is indicated by the law above stated. Hence it may be inferred that solid alloys of zinc and copper are only solidified solutions of zinc and of allotropic copper in each other. The different action of reagents upon alloys and upon the metals constituting them, when in an isolated state, may also be referred to the existence of such allotropic modifications when they are alloyed, as well as to the existence of chemical compounds of the metals in the alloys.

In the tin-gold series of alloys, the curve representing the conductivity has not the typical form of this group of alloys. Beginning from tin there is a gradual decrement

as far as the alloy Sn^3Au^2 ,* then a gradual increment to the alloy SnAu , and then a decrement to SnAu^4 ; and from the alloy containing 2.7 per cent. tin to pure gold, the increase of conductivity is represented by a straight line. These irregularities may be regarded as indicating that the alloys corresponding to the turning-points of the curve are chemical compounds, for they have definite composition; they contain large amounts of both metals: $\text{Sn}^3\text{Au}^2 = 60$ per cent.; $\text{SnAu} = 37$ per cent.; and $\text{SnAu}^4 = 13$ per cent. of tin. Then the specific gravity of the alloy Sn^3Au is almost equal to that calculated, while SnAu expands and SnAu^2 contracts more than any of the other tin-gold alloys. Moreover, the percentage decrement in the conductivity of these alloys between 0° and 100° C. does not conform to the law above stated (p. 943). Tin and gold also dissolve in each other very readily, with evolution of heat.

Matthiessen thus classifies the solid alloys composed of two metals according to their chemical nature.

1. Solidified solutions of one metal in another—lead-tin, cadmium-tin, zinc-tin, lead-cadmium, and zinc-cadmium alloys.

2. Solidified solutions of one metal in the allotropic modification of another—lead-bismuth, tin-bismuth, tin-copper, zinc-copper, lead-silver, and tin-silver alloys.

3. Solidified solutions of allotropic modifications of the metals in each other—bismuth-gold, bismuth-silver, palladium-silver, platinum-silver, gold-copper, and gold-silver alloys.

4. Chemical compounds of the alloys corresponding to Sn^3Au , Sn^2Au and Au^2Sn .

5. Solidified solutions of chemical compounds in each other—the alloys intermediate between those corresponding to the above formulae.

6. Mechanical mixtures of solidified solutions of one metal in another—alloys of lead and zinc containing more than 1.2 per cent. lead or 1.6 per cent. zinc.

7. Mechanical mixtures of solidified solutions of one metal in the allotropic modification of another—alloys of zinc and bismuth containing more than 14 per cent. zinc or more than 24 per cent. bismuth.

8. Mechanical mixtures of solidified solutions of allotropic modifications of the two metals in each other—most of the silver-copper alloys. (Matthiessen, *Brit. Ass.* 1863—*Report on the Chemical Nature of Alloys*, pp. 37-48.)

In accordance with the rule generally obtaining in respect to chemical combination, the metals which present the greatest difference in their general chemical characters are the most capable of existing in combination with each other, and of forming definite compounds. Thus arsenic, antimony, &c., which are the most chlorous of the metals, form numerous definite compounds with the more basylous metals—silver, copper, iron, nickel, cobalt, &c., many of which compounds occur native. (See ARSENIDES AND ANTIMONIDES, i. 316, 370, 591, 1041; ii. 41; iii. 368, 532.)

Some arsenides lose arsenic when heated out of contact with air; but by heating in contact with air they are converted into oxides or basic arsenates, while arsenious acid is volatilised.

These compounds are often formed in metallurgical operations with arsenical minerals containing cobalt, nickel, or iron, and collect in a separate layer between the reduced metal and the sulphides.

The physical characters of alloys, though they always retain the prominent characters of metals, are in some respects very different from those of the metals they contain, and which render these latter useful in the arts. Thus the alloy consisting of copper with half its weight of zinc, is much harder than pure copper, and at the same time sufficiently ductile (see BRASS, ii. 47 *et seq.*). The alloy of copper with one-ninth its weight of tin is much harder than copper, is well calculated for casting, and has sufficient tenacity for the construction of ordnance (see BRONZE, ii. 43 *et seq.*). The alloy of copper with one-ninth its weight of aluminium is hard, tenacious, and malleable (see ALUMINIUM BRONZE, i. 156). The alloy of copper with one-fourth its weight of tin is very hard, and being highly sonorous is well suited for bells, &c. The alloy of copper with half its weight of tin is white, and capable of receiving such a high polish as to be suitable for the reflectors of telescopes. (See SPECULUM METAL, ii. 43.)

The alloy of lead with one-fourth its weight of antimony is readily fusible, much harder than lead, but not brittle like antimony-bismuth or zinc, and is well suited by these characters for type-founding (see TYPE-METAL, i. 316; iii. p. 532). Other alloys will be found described under the heads of the several metals they contain.

The chemical action of reagents upon alloys is sometimes very different from their action upon metals in the separate state; thus platinum, when alloyed with silver, is readily dissolved by nitric acid, but is not affected by that acid when unalloyed. On the contrary, silver, which in a separate state is readily dissolved by nitric acid, is not dissolved by it when alloyed with gold in proportions much less than one-fourth of the alloy by weight.

Analysis of Alloys.—The number of metals which enter into the composition of the various alloys used in the arts is not very considerable, and in most ordinary cases the following systematic mode of testing alloys will serve to afford indications of what metals they contain.

The finely divided substance is covered with strong nitric acid in a glass flask, and the reaction is assisted by the application of a gentle heat.

I. *No reaction takes place, and*

A. The substance remains unaltered, indicating the probable absence of all metals but **gold** and **platinum**.

II. *A reaction takes place, red nitrous fumes being evolved; and in this case:*

B. Solution of the substance takes place without any residue being left, indicating the absence of **gold** (**platinum**), **antimony** and **tin**.

1. The solution may contain all the other metals likely to be present in alloys, &c.; **copper**, **lead**, **silver**, **bismuth**, **mercury**, **arsenic**, **zinc**, **nickel**, **cobalt**, **iron**, **aluminium**.

C. The solution is partial, and the residue is—

2. *Metallic*, or a *black powder*, indicating the presence of **gold**, **platinum**, and perhaps **antimony** and **tin** in small proportions.

3. *White*, indicating the presence of **antimony** or **tin**, and perhaps **gold** and **platinum** in small proportions.

D. No solution takes place, indicating the absence of all metals but **gold**, **platinum**, **antimony**, **tin**, and perhaps **silver** and **lead** in small proportions. The residue may be—

4. *White*, indicating the same as 3.

The solution, 1, is in all cases to be treated in the same manner. When a residue remains undissolved, it is to be separated by decanting off the clear liquid, or by filtration after the excess of acid has been removed by boiling the liquid. The metals are then to be tested for in the clear solution. See ANALYSIS, i. 216.

When, on treatment with nitric acid, there is produced an insoluble residue, 3, it is to be collected upon a filter, washed, and tested for tin, antimony, &c. (See i. 322.)

When the substance is not acted upon by nitric acid, and when it is but partially dissolved, the residue, 2, or the unaltered substance, is to be treated with a mixture of three parts hydrochloric acid and one part nitric acid.

The result of this treatment may be either—

5. *Partial solution* and the separation of a white insoluble powder, chloride of **silver**, or (less probable) chloride of **lead**.

6. *Complete solution*. Both in this and the previous case, the metals belonging to this group A will be dissolved, and the solution may contain **gold** and **platinum**, which should be tested for in the usual manner. (See ANALYSIS, i. 215, and GOLD, ii. 928.)

The chloride solution, 5 and 6, may also contain metals which are only partially dissolved by nitric acid when alloyed with gold or platinum. B. H. P.

METALLURGY. *Hüttenkunde. Metallurgie.*—The art of extracting metals from the various minerals found in the earth, and of converting them into forms suitable for the purposes of the arts, which constitutes metallurgy in its widest range, comprises a number of operations which are of a purely mechanical nature, and which do not come within the province of this work. But many of the most important operations of metallurgy involve processes which are essentially chemical, and it is to the consideration of the general principles upon which these operations depend, that attention will be directed in this article. Information on the mechanical sections of Metallurgy will be found in *Ure's Dictionary of Arts, Manufactures, and Mines*; articles METALLURGY, MINING, and ORES, DRESSING OF.

The metals which are largely used in the arts, viz.: Iron, zinc, copper, lead, tin, antimony, bismuth, nickel, mercury, silver, gold, platinum, are, with the exception of the last two, chiefly found in the state of chemical combination with other substances, constituting a variety of minerals, among which those containing a sufficiently considerable amount of the several metals to admit of their being profitably extracted, are called *ores*, when they occur in sufficient abundance for metallurgic purposes.

The production of the alkali- and earth-metals, which is now carried on more extensively than it was, is a branch of industry appertaining rather to the chemical manufactory than to metallurgy; this is also the case with regard to the production of the compounds of cobalt, chromium, and arsenic which are manufactured from the ores of these metals.

The metallic compounds which are most frequent as ores are:—

1. *Oxides*. Either simple, such as stannic oxide in tin-stone, ferric oxide in hæmatite, or compound oxides, such as ferroso-ferric oxide in magnetic iron ore, and some saline compounds, as carbonates, and, in small quantity, silicates, sulphates, &c.

2. *Sulphides*. Either simple, such as galena, blende, grey antimony; or compound sulphides, such as copper pyrites, zinkenite, miargyrite.

3. *Arsenides*. Generally in small quantity, and mixed with other ores.

These compounds rarely occur in a separate state, but are more or less mixed with other minerals in which they are imbedded, Gang (*Gangue*; *gangart*), constituting masses which are situated in more or less horizontal or vertical positions relatively to the rocks they are associated with, and are accordingly distinguished by the terms bed (*Lager*; *amas*), or lode (*Gang*; *filon*).

The admixtures generally met with in ores are either minerals containing other metals than that of the ore they are associated with, or they are minerals which do not contain any of the metals commonly used for technical purposes, as for instance quartz, some one of the numerous mineral silicates, felspar, hornblende, mica, &c.; carbonates, calc-spar, bitter spar, limestone, &c.; sulphates, heavy spar; fluorides, &c., and portions of the rocks adjoining the lode or bed. Sometimes these latter admixtures are useful in the operations by which the metals are extracted; sometimes they require to be separated mechanically by various preliminary operations. (See ORES, DRESSING OF: *Ur's Dictionary of Arts, Manufactures, and Mines*, iii. 312.)

When the ores of a metal contain admixtures in small proportion of other metalliferous minerals, the operations by which the metal is extracted are in some cases considerably modified, with the view of effecting a separation of the foreign metals; either on account of their value, as in the case of argentiferous lead and copper ores, or because of their prejudicial influence upon the qualities of the metal to be obtained from the ore. (See COPPER, ii. 32; LEAD, iii. 504 *et seq.*)

The physical characters of the metals which it is the object of metallurgical operations to obtain, render it necessary that in most cases they should be melted before being used for practical purposes, and the chemical nature of their ores is such as to require the influence of powerful chemical agencies to effect the separation of the metals from the substances they are combined with. For these reasons, the action of heat in augmenting the chemical activity of substances has been had recourse to in most of the metallurgic operations by which chemical changes are to be effected in the ores or other materials operated upon, and the extraction of metals from their ores has therefore been commonly termed smelting. But there are other methods by which many metals may be extracted, and by which certain of them are to some extent extracted from their ores without the aid of heat. According to these methods, the ores are first operated upon in such a manner as to convert the metal they contain into a compound soluble in water, and from the solution the metal is separated either by the action of another metal upon the solution, or by galvanic action (ELECTRO-METALLURGY, *Ur's Dictionary of Arts, Manufactures, and Mines*, ii. 88). The influence of electricity, however, is chiefly applied in the working of certain metals for particular purposes, as in electroplating, and has not yet been rendered available in the extraction of the ordinary metals from their ores. Among the other methods of extracting metals from their ores in the wet way, the precipitation of copper (ii. 36) and the extraction of silver from its ores by means of sodium-chloride, after the silver in the ores has been converted into chloride (see SILVER), as well as the working of platinum and gold ores by nitro-hydrochloric acid, are the only methods of this kind which are carried on to any extent.

In metallurgic operations, conducted, as is usually the case, in the dry way, or without the presence of water, and with the aid of a high temperature, there are two modes in which chemical alterations are brought about in the ore or other materials operated upon, viz. melting and roasting. In the one case the material is mixed with some substance which decomposes it, when one or other of them is rendered liquid by heat. Thus, for example, galena and metallic iron melted together yield metallic lead and iron-sulphide. When galena is melted with litharge or lead-sulphate in suitable proportions, there are produced metallic lead and sulphurous acid (see *ante*, p. 482). A similar reaction takes place when cupric sulphide and cupric oxide are melted together. (See COPPER, ii. 23 *et seq.*)

In the other operation, viz. roasting, the ore, or other material, is subjected to the joint action of heat and of a gaseous substance capable of producing a chemical alteration calculated to facilitate a subsequent operation. Thus, for instance, in copper smelting, the ores consisting of sulphides, are roasted in contact with atmospheric air so as to convert them to a great extent into oxides, and in the subsequent melting operation the cuprous oxide is again converted into sulphide by reaction with the

iron-sulphide remaining unoxidised, and is thus separated from the ferric oxide produced in the roasting. In the smelting of lead also, the galena is first roasted in contact with atmospheric air, and is thus partially converted into oxide and sulphate, which, in the subsequent melting operation, react with the remaining sulphide as above indicated.

In some cases the operation of melting is conducted with the view of effecting oxidation, as in the separation of antimony from gold, or of lead from gold and silver in cupellation (see *ante*, p. 508 *et seq.*). Roasting also is sometimes conducted with the object of effecting reduction, as in the conversion of metallic sulphates and arsenates into sulphides and arsenides by means of carburetted gases. But, as a general rule, the chief ultimate effect produced by roasting is oxidation, or some corresponding change; while the ultimate effect produced by melting is most frequently reduction. These operations are in some way involved in the extraction of all metals from their ores; a description of the general conditions under which they are conducted, and the general features of the chemical processes which take place under those conditions, will therefore exhibit the chief chemical principles of metallurgy. More detailed information will be found under the heads of the respective metals.

ROASTING OF ORES AND METALLURGIC PRODUCTS.

Ores and intermediate products are roasted either in the state of coarse powder, or as large lumps, according to their nature. The degree of heat applied is not in any case sufficient to cause fusion, or aggregation of the mass, and sometimes it is necessary to keep the material operated upon stirred about, so as to expose fresh surfaces to the action of the gas by which chemical alteration is effected.

Roasting is conducted, sometimes in kilns, sometimes in reverberatory furnaces specially constructed for the purpose, and sometimes the materials are merely piled up in heaps with alternate layers of fuel, which are ignited and allowed to burn slowly until consumed.

Oxidising roasting is always effected by means of a current of heated atmospheric air made to pass over the material at a suitable temperature. The chemical change produced by roasting is either a mere combination with oxygen, as in roasting magnetic iron ore, which is thus converted into ferric oxide; or it may be attended with the separation, more or less complete, of some constituent of the material operated upon, as in roasting sulphides, when a portion of the sulphur is converted into sulphurous acid and volatilised, while the metal is converted into oxide, and another portion of the sulphur is oxidised into sulphuric acid, which remains combined with the metallic oxide.

The different metallic sulphides present very different characters under these conditions: thus—

Iron-protosulphide is partially converted into ferrous sulphate: this at a higher degree of heat is decomposed into sulphurous acid, which is volatilised, and basic ferric sulphate, and ferrous oxide. At a still higher temperature the basic sulphate may be also decomposed, yielding at last ferric oxide. In operations on the large scale, however, it is very difficult to effect the entire separation of sulphur from iron-sulphide by roasting, even when the material is finely divided, the heat gradually applied, and the surface frequently changed by stirring meanwhile.

Zinc-sulphide undergoes oxidation very slowly, yielding a mixture of sulphate and oxide, which at a higher temperature loses sulphuric acid, and may be eventually converted into pure oxide. This result, however, is more difficult to obtain than in the case of iron-sulphide; but the roasting of zinc-sulphide is not so troublesome, inasmuch as it is less liable to undergo partial fusion than iron-sulphide is.

Copper-sulphide, when carefully roasted, is converted into a mixture of cuprous oxide and cupric sulphate. So long as sulphurous acid is being produced by the oxidation of sulphur, cupric oxide cannot be formed: for cupric oxide heated in contact with sulphurous acid is partially reduced, cuprous oxide and cupric sulphate being produced; but so soon as all the copper-sulphide has been converted into such a mixture, the cuprous oxide begins to be further oxidised. At a higher temperature, the cupric sulphate undergoes decomposition, sulphuric acid being more or less expelled. In the imperfect roasting of copper-sulphide, which is generally effected when ores containing that substance are operated upon on the large scale, the result is a mixture of cuprous oxide, cupric sulphate, copper-sulphide, and metallic copper. The latter appears to be produced in those places where the cuprous oxide is more highly heated, while surrounded by an atmosphere of sulphurous acid, than would be sufficient to reduce cupric oxide to cuprous oxide under the same condition.

Lead-sulphide is difficult to roast, since it is very liable to aggregate together,

yielding a mixture of lead-sulphate and lead-oxide, from which the sulphuric acid cannot be expelled, even when it is heated so high as to melt.

Bismuth-sulphide is so fusible that it is very difficult to roast completely.

Antimony-trisulphide is also very difficult to roast for the same reason. There is generally produced a mixture of trioxide, pentoxide, and sulphide of antimony. If the heat be high, a portion of the pentoxide is volatilised.

Arsenic-sulphide and *trisulphide* are decomposed by roasting, yielding arsenious and sulphurous acids, both of which are volatilised.

Mercury-sulphide is converted by roasting into metallic mercury and sulphurous acid.

Gold-sulphide undergoes the same alteration by roasting.

Silver-sulphide is entirely converted into metallic silver. But when it is roasted together with other sulphides, such as iron- or copper-sulphide, some silver-sulphate is always produced, which by increase of temperature is decomposed into metallic silver, sulphurous acid, and oxygen.

Nickel-sulphide can be easily converted by roasting into a mixture of nickel-oxide and peroxide, with only a small admixture of unaltered sulphide. So long as sulphurous acid is generated abundantly, nickel-oxide only is produced, and this afterwards becomes peroxidised.

Cobalt-sulphide behaves in a similar manner to nickel-sulphide, except that some cobalt-sulphate is always produced.

In the roasting of sulphides, modifications of the chemical changes are often effected when reducing gases, such as carbonic oxide or hydrocarbons, are mixed with the atmospheric air; also, perhaps, when water vapour is present, as is almost always the case in this operation as conducted on the large scale.

The precise chemical alterations which arsenides and phosphides undergo when subjected to oxidising roasting, are less known than those of sulphides; but, as a general rule, arsenic is more difficult to separate than sulphur, and phosphorus can be separated only to a very small extent, on account of the stability of phosphoric acid at high temperatures.

Volatilising roasting. The sulphides containing the largest proportions of sulphur, such as iron-pyrites, &c., lose part of their sulphur by direct decomposition, in consequence of the mere action of heat. Hydrated compounds, carbonates, &c., are also decomposed in the same manner. But more generally the volatilisation of some constituent of the material roasted, is the result of previous chemical alteration, and its conversion into a volatile compound by the chemical action of the atmosphere in which the operation is conducted.

Chloridising roasting is effected by means of an atmosphere containing chlorine, hydrochloric acid, or chlorides. Silver ores are often subjected to this treatment, to convert the silver into chloride. At the same time, iron is partially volatilised as ferric chloride; arsenic, antimony, zinc, tin, bismuth, mercury, chromium and sulphur are also volatilised as chlorides.

Reducing roasting. When iron ores are heated in an atmosphere of reducing gases, such as carbonic oxide or hydrocarbons, metallic iron is produced; and in iron smelting this change always precedes the actual melting. When such ores contain zinc as well as iron, both metals are reduced, and the zinc is volatilised at a sufficiently high temperature. Under similar conditions arsenates and arsenites yield a portion of their arsenic in the metallic state. This is also the case with antimonates, tellurates, selenates, or sulphates.

MELTING OF METALLURGICAL PRODUCTS FOR THE EXTRACTION AND SEPARATION OF METALS.

Ores are rarely subjected to the operation of melting without having previously undergone some other treatment, such as roasting, &c. This preliminary treatment is in some cases only the earliest stage of the melting operation, as in the smelting of iron ores, which, in the upper parts of the blast-furnace, are subjected to the action of heat and reducing gases before sinking down to that part of the furnace where fusion takes place. (See IRON, *ante*, pp. 357, 361.) But in such cases, the chemical nature of the processes involved in the roasting and the melting is exactly the same as when these operations are conducted separately.

The chemical alterations which take place in the operation of melting sometimes result in the separation of a metal in the state of regulus, sometimes only in the partial separation of the substances combined with it, and the production of a matt (*Stein*; *malle*), or compound containing a larger proportion of metal than the material operated upon. (See COPPER, ii. 23 *et seq.*) These results are often due solely to the mutual action of the several constituents of the ore, which has undergone

METALLURGY.

Preparatory treatment of roasting, &c.; but in most cases it is necessary to add some substance by means of which the desired result may be produced. The kind of substance to be added will of course be determined by the nature of the material to be operated upon, and by the kind of chemical alteration to be effected. Thus in smelting antimony ore, consisting of the trisulphide, it is mixed with scraps of metallic iron, by reacting with which it yields metallic antimony and iron-sulphide.

In all cases it is essential that in the melting operation there should be not only a chemical alteration of the materials, but also a physical separation of the resulting products. It is not often that this can be effected by the volatilisation of some one or more of the products. More frequently they are all fixed, and in this case they can be obtained separate only when they differ in specific gravity, and are also incapable of mixing with each other while in the liquid state. It is therefore always necessary, that in melting operations the whole of the materials should be rendered so liquid that such a separation may readily take place. The high specific gravity of the metals which it is the object of the metallurgist to obtain, is favourable to their separation as regulus, from the other products of the melting operation. The sulphides of these metals are also sufficiently dense to separate readily in the state of matt from most of the other products of melting, though their specific gravity is less than that of the metals.

With the object of facilitating the separation of the several products of the chemical action which takes place in melting operations, the ore or other material is generally mixed with some substance which has the capability of facilitating the liquefaction of the products formed, and their separation into distinct layers. Such an admixture added with the object of rendering some part of the material operated upon capable of being melted, or more readily fusible than it would be otherwise, is termed a flux (*Zuschlag*; *fondant*).

In the first melting of ores consisting chiefly of metallic sulphides, the product obtained is not always the metal, even when the ore has been previously roasted. More frequently a matt or mixture of sulphides is obtained, and if any metal is reduced to the state of regulus, the matt forms a separate layer above it. In melting ores containing much antimony, arsenic, &c., together with other metals, a third layer is sometimes formed, which separates between the regulus and the matt, and is called *Speiss*.

But ores very generally contain, besides the actual metalliferous portion, a variety of siliceous or earthy admixtures, originating from the rocks and minerals with which they are naturally associated. These admixtures cannot be entirely separated by mechanical means, and since they are generally infusible or difficult to melt, they require to be converted into compounds which are sufficiently fusible, and of less specific gravity when melted, than the other products to be obtained. The fluxes added with this object are generally either—

Siliceous, such as quartz, sandstone, &c., or

Earthy, such as lime, limestone, clay, &c., according to the nature of the substances to be separated; by this means a fusible vitreous compound consisting of earthy silicates is formed, which is termed slag. Sometimes special fluxes are used, such as fluor-spar, alkaline salts, &c. (see p. 952).

The addition of fluxes in the melting operation is also advantageous in facilitating the fusion of the material operated upon, and the separation of the several products formed. Moreover, the resulting slag, being of less specific gravity than the other products, collects above them, and thus furnishes a protection against the oxidising action of the furnace gases, which is often a further advantage.

The melting operation is generally conducted either in shaft furnaces, where the materials are mixed with the fuel, or in reverberatory furnaces, where they are heated in a separate chamber by means of the flame and gaseous products of combustion. Sometimes crucibles are used in order to keep the materials entirely out of contact with the fuel.

Reducing melting is generally effected, in the case of metallic oxides, by the joint action of heat and the carbon, carbonic oxide, hydrocarbons or hydrogen contained in or resulting from the combustion of the fuel used in the operation. By reason of the unequal degrees of chemical stability of the several metallic oxides, the temperatures at which they are reduced by those substances differ considerably. The oxides of lead, bismuth, antimony, nickel, cobalt and copper are reduced by carbon within the range of red heat; while those of iron, manganese, chromium, tin, and zinc require more or less intense degrees of white heat.

The mode in which reducing melting is conducted varies according as the oxide is easily fusible or infusible at any temperature that can be attained in the operation. In the first case the material can be intimately mixed with carbon; in the second case this cannot be effected, and the reduction is to a great extent due to the carbonic oxide resulting from the combustion of carbon with a scanty proportion of air. (See *Iron*, p. 358.)

METALLURGY.

The reduction of metallic sulphides by melting is effected principally by means of metallic iron. Lead-sulphide melted with iron in equivalent proportions yields metallic lead, and iron-sulphide. With two equivalents of iron, there are produced metallic lead and iron-sulphide containing metallic iron mechanically mixed. Zinc-sulphide is completely decomposed by iron, but a very high temperature is required. Cuprous sulphide is partly decomposed by melting it with metallic iron, and there are produced a matt consisting of cuprous sulphide and iron-sulphide, and some metallic copper. The sulphides of copper and iron yield, on the contrary, a matt consisting of cuprous sulphide, iron-sulphide and metallic iron. Lead-sulphide with two equivalents of copper yields a matt consisting of cuprous sulphide and metallic lead. Equal equivalents yield metallic lead and a matt consisting of cuprous sulphide and lead-sulphide.

Similar reactions take place between zinc-sulphide and copper.

Lead-sulphide is entirely decomposed by melting with an excess of tin, but in equal equivalents it is only partly decomposed, and there are produced an alloy of tin and lead and a matt consisting of tin-sulphide and lead-sulphide.

The metals of the alkalis exercise a much more energetic action upon metallic sulphides when melted with them, and though they cannot be employed in ordinary metallurgical operations, a similar action may be produced to some extent by means of a mixture of the alkalis and carbon (black flux). Thus, when a metallic sulphide is melted with a sufficient quantity of alkaline earth or alkali mixed with carbon, the metal is reduced, since the sulphur combines with the alkali- or earth-metal, while the oxygen of the latter combines with carbon. When an alkali is used, more or less of the metallic sulphide generally remains undecomposed and dissolved in or combined with the alkaline sulphide.

Oxidising melting is practised with the object of separating one metal from another, or of separating sulphur from metallic sulphides by converting the sulphur, or the metal to be removed, into oxides, which may either be volatile as sulphurous acid, fusible as oxide of lead, or capable of being rendered fusible by combination with certain substances added as fluxes.

Atmospheric air is the oxidising agent most commonly employed; but sometimes other substances are also used, which are capable of yielding oxygen at a high temperature, especially when in the liquid state and in contact with the substances to be oxidised. Among these are lead-oxide and oxy-salts, cupric sulphate, ferrous sulphate, basic ferrous silicate, nitrates, &c.

The following examples will serve to illustrate the mode in which these oxidising agents are employed in the melting operation.

Atmospheric air.—Compounds of gold or silver with antimony, arsenic, or sulphur, when melted in a sufficiently heated current of atmospheric air, are decomposed, and the metals are obtained in the pure state.

When atmospheric air is passed over the surface of melted copper containing iron, cobalt, lead, antimony, arsenic, and sulphur, the three latter are volatilised as oxides, and a more or less liquid layer or scum collects upon the surface of the metal, consisting of ferric oxide, cobalt- and lead-oxides, antimonious oxide, and cuprous oxide, until the copper remains almost pure. The greater the quantity of lead in proportion to the other impurities, the more liquid is the layer which collects on the surface; and the smaller it is, the thicker is this scum. In both cases the scum must be removed from time to time, so that a fresh metallic surface may be exposed, and if it is not sufficiently liquid to be removed by the current of air, the edges of the convex surface of melted metal where it principally collects must be raked off.

When alloys of gold or silver with lead or bismuth are exposed in a melted state to a current of air, the latter metals are oxidised, and pure gold or silver remains, together with a slag of lead-oxide. A portion of the oxide is volatilised, and in the case of silver-alloys especially, a small quantity of this metal is also volatilised. When small quantities of other metals, such as iron, cobalt, copper, &c., are present in such alloys, they are oxidised, and the oxides are dissolved by the oxide of lead or bismuth.

When a compound of arsenic, iron, cobalt, and nickel is melted in a current of air, so that the ferric oxide and cobalt-oxide produced may be dissolved by melted borax, partly covering the surface of the melted metal, arseniferous nickel may be obtained; but the whole of the arsenic cannot be separated, because, in proportion as it is separated, the melting point of the remaining metal becomes higher, and it finally solidifies.

Lead-oxide.—When litharge is melted with easily oxidisable metals, they are oxidised by the decomposition of the lead-oxide, a part of the lead-oxide is reduced, and a slag consisting of lead-oxide and the oxide of the metal is produced; but the perfect oxidation of metals possessing little affinity for oxygen cannot be effected in this way, without using a large excess of litharge.

Metallic sulphides or arsenides melted with litharge, yield sulphurous and arsenious acid, which are volatilised, and alloys of the metals with lead.

Iron-sulphide melted with thirty parts by weight of litharge is entirely oxidised, sulphurous acid being volatilised, while the iron remains probably in the state of ferrous oxide combined with the excess of lead-oxide, forming a slag which collects over the reduced lead. With less lead-oxide the decomposition is incomplete, and a part of the iron-sulphide passes into the slag.

The oxidation of cuprous sulphide in this way requires 25 pts. by weight of litharge.

The oxidation of copper pyrites requires at least 30 pts. of litharge. When less is used, the copper-sulphide remaining undecomposed is not dissolved by the slag consisting of lead-oxide and cuprous oxide, but forms a matt with a portion of the metallic lead.

Antimony-trisulphide is entirely decomposed by melting with about twenty-five times its weight of litharge, yielding antimonious acid and sulphurous acid.

Tin-sulphide requires for perfect decomposition 30 pts. of litharge.

Zinc-sulphide requires 25 pts. of litharge.

Bismuth-sulphide when melted with litharge yields sulphurous acid and an alloy of bismuth and lead, but no bismuth-oxide.

Lead-sulphide is decomposed by melting it with about twice its weight of litharge, the whole of the lead being separated in the metallic state, while sulphurous acid is volatilised. When the lead-sulphide is in excess, it mixes with the metallic lead.

Arsenic-trisulphide melted with from 50 to 60 pts. of litharge is completely oxidised, yielding sulphurous acid and arsenious acid.

Other metallic oxides react with metallic sulphides in a similar manner to litharge, and, as a general rule, when a metallic sulphide is melted with a metallic oxide, the former is oxidised to a greater or less extent, and the relative quantity of the oxide produced depends upon, 1st, the relative quantity of oxide used, and 2nd, the relatively chlorous and basylous characters of the metals and of sulphur and oxygen.

Lead-carbonate acts in the same manner as lead-oxide upon metallic sulphides and oxides.

Lead-silicate also acts in the same manner, but a much larger quantity is required to produce the same effects as litharge. The slags produced in this case are double silicates containing both metals.

Lead-sulphate is a still more powerful oxidising agent than litharge, since the decomposition of its sulphuric acid yields an additional quantity of oxygen. When it is melted with lead-sulphide in due proportions, the products are only metallic lead and sulphurous acid.

Cupric sulphate heated with metallic sulphides generally exercises an oxidising action like lead-sulphate.

Copper-sulphide heated with cupric-sulphate is converted into copper, cuprous oxide, cupric oxide, basic cupric sulphate, &c., according to the proportions and temperatures. Silver-sulphide is also converted into sulphate in the same way; but metallic silver may be separated by the action of cuprous oxide.

Ferrous sulphate acts in a similar manner with metallic sulphides.

Nitrates are too costly to be generally used in metallurgical operations, though they are the most powerful oxidising agents in melting operations.

Basic ferrous silicate is one of the most important oxidising agents in metallurgical operations. For instance, when iron containing carbon, silicon, sulphur, and other readily oxidisable substances, is strongly heated with a melted basic ferrous silicate, half of the ferrous oxide is decomposed, and the oxygen thus eliminated combines with the above-named impurities of the iron, forming carbonic oxide, silica, and sulphurous acid.

Solvent melting is practised chiefly with the object of separating certain parts of the materials operated upon in the extraction of metals. The substances used for this purpose are principally metallic oxides, silica, alkaline and earthy salts, silicates, metals, and sulphides.

Metallic Oxides.—Easily fusible oxides, such as lead-oxide, &c., melted with other less fusible oxides, at sufficiently high temperatures, dissolve the latter to a greater or less extent, sometimes forming saline compounds. Certain sulphides are also dissolved by lead-oxide and bismuth-oxide without decomposition, forming compounds termed oxysulphides. In metallurgical operations, it is only the solvent action of lead-oxide which is of special importance, and that chiefly in the purification of silver. (See p. 951.)

As a general rule, all oxides which are readily fusible, like bismuth or antimony oxides, may be mixed with lead-oxide in all proportions by fusion, but the less fusible oxides yield with lead-oxide difficultly fusible mixtures.

Tin-sesquioxide dissolves in four parts by weight of lead-oxide, forming a viscid liquid; with eight parts of lead-oxide it forms a very fusible mixture.

Zinc-oxide dissolves in seven parts of lead-oxide, forming an easily fusible mass.

Ferric oxide dissolves in four parts of lead-oxide, forming a viscid liquid.

Cuprous oxide with one and a half times its weight of lead-oxide forms a very liquid compound, and is probably soluble to a still greater extent.

Among the metallic sulphides, those of gold, silver, copper, &c., do not dissolve in melted lead-oxide (see above). All the other sulphides are more or less dissolved by it. Antimony trisulphide appears to be especially soluble in lead-oxide.

Metals.—Lead is the metal principally used as a solvent in certain melting operations. It has the property, when melted with argentiferous and auriferous sulphides in due proportion, and by sufficiently intimate mixture, of dissolving out the silver and gold. This effect is due to the decomposition of the gold and silver sulphides by lead at a high temperature, in such a manner that these metals are eliminated while lead-sulphide is formed, while, at the same time, there is scarcely any decomposition of iron-sulphide or copper-sulphide in the same way. The products of the melting are therefore argentiferous or auriferous lead containing lead-sulphide, and a matt consisting of copper-sulphide and iron-sulphide. Gold or silver may also be extracted from metallic copper by means of lead, but in a less direct manner. Both the gold or silver and the copper are dissolved by the melted lead; but in the solidification of this mixture, the greater part of the lead separates, and there is produced a mechanical mixture of lead containing gold or silver, and of an alloy consisting of lead with three times its weight of copper, containing much less silver. When this mechanical mixture is heated to the melting point of lead, this metal may be separated, together with the gold and silver, while the copper-lead alloy remains behind.

Metallic sulphides, such as iron-sulphide, &c., may be used in the same manner as metallic lead for extracting gold or silver from ores or metallurgic products. Thus when silver ores containing large admixtures of gang, in the melting of which alone the greater part of the silver would pass into the slag, are melted with iron-sulphides, the silver is dissolved as sulphide, and the gangue forms a slag containing but little silver.

Silica is rarely used alone as a solvent in the melting operation, silicates or earths being generally present, with which it forms compound silicates. Its action in such cases is therefore indirect, and depends more upon the nature of the silicate produced. (See p. 964.)

Earthy oxides, such as baryta, strontia, lime, magnesia, and alumina, respectively form with silica sparingly fusible or infusible compounds, according as the basylous character of the earth in relation to silica, is greater or less, and according to the proportions of earth and silica. The fusible baryta-silicates contain from 30 to 70 per cent. silica; the others are infusible. Strontia-silicates are much less fusible; that containing 55 per cent. silica forms a white opaque mass. Among the lime-silicates the limits of fusibility are between 25 per cent. and 47 per cent. of lime. Magnesia-silicates, and especially alumina-silicates, are infusible, and soften only at a full white heat.

Metallic oxides form compounds with silica which present similar differences in fusibility, according to the greater or less basylous character of the oxide in relation to silica and the proportions in which they are combined. Thus ferrous silicates with from 42 to 82 per cent. ferrous oxide, are easily fusible, while ferric silicates are infusible. Cuprous silicate is fusible only when it contains 70 per cent. cuprous oxide. Cupric silicates are probably infusible, but on account of their liability to undergo reduction, they cannot easily be produced. Zinc-silicates and tin-silicates are infusible. Lead-silicates containing from 54 to 88 per cent. of lead-oxide melt more or less easily. Bismuth-silicates are still more fusible. Antimony-silicates are sparingly fusible.

Alkaline carbonates dissolve most metallic oxides to some extent, the carbonic acid being also partly expelled at a red heat. With a sufficient excess of alkaline carbonate some of these compounds are easily fusible (Berthier). Ferrous oxide melted with 6 pts. of potassium-carbonate yields a greenish crystalline mass. Ferric oxide appears to be insoluble in melted alkaline carbonates. Tin-oxide fuses readily with 5 pts. by weight of potassium-carbonate; zinc-oxide is less soluble. Cuprous oxide and cupric oxide melt easily with 3 pts. of potassium-carbonate. Lead-oxide mixes in all proportions with melted alkaline carbonates.

Borax is a very efficient solvent in melting operations, but is too costly to be much used in metallurgy. Baryta, lime, magnesia, and alumina are dissolved in considerable proportions by melted borax, forming more or less fusible vitreous masses (Berthier). Silica and fire-clay melt together with borax at high temperatures. All the metallic oxides which are not reduced by heat alone, are dissolved to a greater or less extent by melted borax. Ferrous oxide or ferroso-ferric oxide, melted with an equal weight of borax, forms a compact crystalline mass. Manganous oxide is dissolved in very considerable amount by borax. Lead-oxide and borax melt together in all proportions.

Fluor-spar is important as a solvent in melting operations, on account of its capability of dissolving about half its weight of silica at a high temperature, without having any tendency to combine with or dissolve metallic oxides. Fluor-spar is, therefore, a very suitable flux in the melting of ores which are refractory on account of the silica they

contain. Fluor-spar also dissolves sulphates which are infusible or difficult to fuse alone, such as heavy spar, gypsum, &c. Thus with $1\frac{1}{2}$ pt. barium-sulphate, 4 pts. anhydrous calcium-sulphate, or 10 to 15 pts. lead-sulphate, fluor-spar forms vitreous masses which are tolerably fusible.

Silicates.—The earthy and alkaline silicates in a melted state have the capability of dissolving metallic oxides in considerable proportions, forming when cooled the vitreous or stony masses generally called slags. In metallurgic operations it is of importance that there should be a proper proportion between the silica and earthy bases in the materials from which the slag is produced in melting, in order that its solvent action upon the metallic oxides present may be neither too great nor too little. The former might be the case if there were too much silica; the latter if there were too little. Siliceous slags are generally of such composition that the ratio of the oxygen in the bases to that in the silica is approximatively either as 1 : 3, 1 : 2, or 1 : 1. From the nature of the silicates generally and from the circumstances under which slags are produced in metallurgical operations, it is of course rarely that they are definite chemical compounds. Slags may indeed contain definite compounds, but in almost all cases they are merely heterogeneous mixtures of such compounds with other adventitious substances, and therefore the attempt to represent their composition by formulæ is not only useless but deceptive. The utmost that can at present be said with regard to the composition of slags is, that there are certain tolerably constant relations between the fusibility, &c. of slags and the ratio of the oxygen in the bases to that in the silica. The numerous analyses of slags from different metallurgic operations all afford evidence in favour of this view, and from among them the following selections will serve to represent the general composition and limits of variation in slags.

Names of Works.	Blast furnace slags, from iron smelting.				Slags from copper smelting.			Lead slag.

Ratio of oxygen in bases to oxy- gen in silica	1 : 1	1 : 1.6		1 : 2.5	1 : 1	1 : 2.5	1 : 2.5	1 : 2

The solvent action of earthy silicates upon metallic oxides is especially serviceable in effecting the separation of the ferrous oxide, produced by the oxidising roasting of ores and certain products of metallurgic operations, such as copper-matts, &c. Thus when a mixture of ferric oxide, cuprous oxide, and a silicate containing excess of silica is subjected to reducing melting, the cuprous oxide and the ferric oxide are both reduced, the former yielding metallic copper, and the latter ferrous oxide, which combine with the silicate, forming a fusible slag which admits of the metallic copper separating out and collecting together in mass below it. Manganic oxide, or cobalt-oxide, &c., would behave in the same manner as ferric oxide; and any easily reducible oxide, in the same manner as cuprous oxide.

Silicates also exercise a solvent action upon the gangue mixed with ores. Thus for example, when an ore consisting of galena and gangue is melted, with addition of ferric oxide and suitable slags, the latter dissolve the gangue, the ferric oxide is reduced to ferrous oxide, which reacts with the lead-sulphide, and oxidises a portion of the sulphur to sulphurous acid, which volatilises, while the metallic iron produced at the same time, separates the lead from combination with the remaining sulphur, and forms iron-sulphide. In this case all the different reactions produced in melting operations take place together.

As a general rule it may be stated, that when mixtures of an oxide with another oxide which is more easily reduced, and of silicates containing a sufficient amount of silica, are subjected to reducing melting, the least easily reducible oxide is dissolved by the silicate and forms slag, while the more easily reducible oxide yields metal. To

obtain this result, however, it is necessary that the silicate should be present in sufficient amount, and that its melting point should be higher than the temperature at which the more easily reducible oxide is decomposed, and lower than that at which the less easily reducible oxide is decomposed. If there were a deficiency of silicate, the whole of the ferrous oxide would not be converted into slag, and a portion of it would be reduced to the metallic state. If the silicate melted before the cuprous oxide had been reduced, part of the latter would pass into the slag; and if it did not melt till after ferrous oxide had been partly reduced, the copper would be mixed with iron.

Slags should in general be more easily fusible, or at most not less fusible than the other products of the melting operation; but the actual degree of fusibility will vary considerably, according to the temperature requisite in the operation. The following table contains a summary of the more important results obtained by Plattner in his investigation of the fusibility of various silicates and slags:—

Temperature of formation.	Melting point.	Silica.	Baryta.	Lime.	Magnesia.	Alumina.	Ferrous oxide.	Manganous oxide.	Lead oxide.	Ratio of oxygen in bases to oxygen in silica.
2200° C.	. .	29.1	70.9	1 : 2.1

The temperatures given as those at which these silicates were formed and melted refer to the melting points of platinum 2534° C., gold 1102° C., silver 1023° C., and lead 334° C., adopted by Plattner as the standards of comparison in his experiments.

The fluidity of slags differs very considerably, and it is often of great importance in practice. The mode in which they solidify also is of still greater importance. Some are very liquid, but change at once by reduction of temperature from the liquid to the solid state; others are less liquid, and solidify gradually, passing through several stages of viscosity.

The former always contain a smaller proportion of silica than the latter; and the characters of slags, while in the melted state, and after solidification, often furnish the practised metallurgist with indications as to whether the materials he is operating upon are duly proportioned or not.

Slags are sometimes amorphous, sometimes crystalline. The former are often glassy; the latter present an appearance resembling certain rocks, such as lava, and in composition they often approximate to augite, olivin, felspar, &c.

SUBLIMATION AND DISTILLATION.

Volatilisable metals and metallic compounds are in some cases separated from their ores by means of that character. Thus arsenious acid, arsenic sulphide, and cinabar are separated in this way from other substances with which they may be mixed or combined. The native compounds of iron with arsenic are decomposed by heat, yielding metallic arsenic, which is volatilised, while a lower arsenide remains. Arsenical

pyrites heated in a close vessel yields arsenic sulphide at first, and finally metallic arsenic, about half the sulphur and rather less of the arsenic remaining combined with the iron. When mercury ores are heated with some substance capable of forming a fixed compound with any constituent of them which is capable of being volatilised in combination with the metal, metallic mercury distils off. Zinc-carbonate, intimately mixed with carbon and exposed to a white heat, is decomposed after losing its carbonic acid; the carbonic-oxide produced by the partial combustion of the carbon reduces the zinc-oxide, and the metal is volatilised.

ELIQUATION AND CRYSTALLISATION.

These operations are practised with the object of separating mixtures of substances which have different melting points, or which solidify at different temperatures. Argentiferous lead is separated from a mixture of lead and copper containing silver (see p. 953), by heating it in such a manner that when the lead melts, it can flow away from the alloy of copper and lead which remains solid. Silver is separated from argentiferous lead by crystallisation, since the alloy of lead with the largest proportion of silver does not solidify until the alloy of lead with the smallest proportion has separated in crystals. (See p. 504.)

The metallurgical operations already treated of being all conducted with the aid of heat, involve the use of fuel as a source of heat; and it is therefore an object of great importance to apply it to this purpose in the most efficient and economical manner. The general principle by which the relative value of different kinds of fuel may be determined, and the conditions under which they may be rendered most efficacious, have been already considered. (See FUEL, ii. 718 *et seq.*) It now only remains to refer simply to the means of augmenting the efficacy of fuel beyond its natural capability, so far as relates to the production of high temperatures by the application of heated air in the combustion of fuel. The advantage gained in this way always involves the consumption of a proportionately larger amount of fuel according to the degree of temperature produced; but since the metallurgic operations which require a very high temperature can be conducted much more rapidly in proportion as the temperature is increased, the saving of fuel effected by using a high temperature is referable to the larger quantity of material which can be worked within a given time, compared with what can be worked within the same time at a lower temperature.

Whenever it is necessary to use fuel in such a manner that only a portion of its heating power is rendered effective, as in most of the operations connected with the manufacture of iron, a very great economy can be effected by using the waste gases for the purpose of heating the air with which the furnaces are fed, instead of allowing those gases to escape without producing any useful effect. The heat thus communicated to the air with which the furnaces are fed has the effect of raising the temperature produced in those furnaces to a degree far higher than can be produced by the mere combustion of the fuel used. This augmentation of temperature is of course proportionate to the increased temperature at which air is supplied to the furnaces, and since the production of a very high temperature is the essential condition by which economy of fuel is to be attained in the manufacture of iron, the means of insuring this object are of the highest importance. (See IRON, iii. 362 *et seq.*, and FUEL, ii. 729.)

In many metallurgic operations, the use of gaseous fuel obtained by burning coal, &c., so as to convert it into carbonic oxide and hydrocarbon gases, is capable of being made a very valuable means of effecting economy in fuel, and at the same time of obtaining more advantageous results as regards the metals produced; but as yet little progress has been made in this direction compared with the capabilities which exist for such a use of fuel.

The use of air containing a larger amount of oxygen than atmospheric air would also be a very efficient means of economising fuel, especially in operations requiring high temperatures or intensity rather than quantity of heat. Some attempts have already been made to realise the advantages of such a practice, but they have not hitherto been attended with any such success in relation to the larger metallurgic operations as to require more than a passing mention. (See FUEL, ii. 725.)

The metallurgic operations which are conducted without the aid of a high temperature, and by the agency of water or other solvents, according to what is termed the wet way, are but few, viz. the extraction of platinum and silver, the separation of gold from silver, and to a less extent the extraction of copper from some of its ores.

SOLUTION AND PRECIPITATION.

By the first of these operations silver is extracted from its ores as sulphate, or by means of a solution of sodium-chloride, after the metal has been converted into chlo-

ride. Platinum is also extracted from its ores by means of nitro-hydrochloric acid, and silver is separated from gold by treatment with nitro-hydrochloric acid, which dissolves only the latter metal; or when the silver amounts to more than three times as much as the gold, by means of nitric acid (see GOLD, ii. 925), which dissolves only the silver, this operation being termed *parting*. Copper is also extracted from poor ores by converting it into chloride or sulphate, and dissolving these salts out with water. (See COPPER, ii. 36.)

Another operation involving solution is the extraction of gold and silver from their ores by means of mercury, which is frequently practised under the name of an *amalgamation*, since the solution of the metals by mercury depends upon the formation of an amalgam, which dissolves in excess of mercury. (See GOLD, ii. 925, and SILVER.)

Precipitation is practised for the separation of metals from the solutions obtained from ores as above mentioned. Thus copper is precipitated in the metallic state by means of metallic iron, which decomposes the copper-compound held in solution. This operation is termed *cementation*. (See COPPER, ii. 36.) Platinum is separated from solution as ammonio-chloride, by precipitation with solution of sal-ammoniac; silver as chloride, by means of solution with salt, or hydrochloric acid; and gold, in the metallic state, by means of ferrous sulphate. (See GOLD, ii. 925.)

The various operations of metallurgy which are conducted by means of electrolysis, such as electroplating, electrogilding, and electrotyping, depend upon the principles which have already been discussed in general terms in the article ELECTRICITY (ii. 414 *et seq.*, and 437); and more precise details will be found in *Ure's Dictionary of Arts, Manufactures, and Mines*, article ELECTRO-METALLURGY.

The methods of manufacturing aluminium, magnesium and sodium, &c., will be found in the articles devoted to the general chemistry of those metals. B. H. P.

METALS, ATOMIC WEIGHTS AND CLASSIFICATION OF.

GROUP I. Monad metals.—The received atomic weights of the non metallic monads, fluorine, chlorine, bromine, and iodine, or 19, 35.5, 80, and 127, are merely the relative weights of each of them which have the same gaseous bulk as the unit of hydrogen. These four halogen elements, which may be considered as chlorous or electro-negative varieties of hydrogen, have the characteristic property of replacing hydrogen and one another, in a great variety of compounds, by an equivalent substitution of volume for volume, atom for atom. The fluoride, chloride, bromide, and iodide of hydrogen are composed of equal volumes of halogen and hydrogen united without condensation, one volume or atom of chlorine, for instance, uniting with one volume or atom of hydrogen, to form two volumes of hydrochloric acid, HCl. These two volumes constitute the molecule of hydrochloric acid, which is usually regarded as a chloro-derivative of the molecule of hydrogen, H₂, and taken as a convenient standard of comparison for two-volume molecules in general.

The metals lithium, sodium, potassium, rubidium, cesium, and silver are correlative to the above halogen elements, and accordingly may be looked upon as basylous or electro-positive varieties of hydrogen. Their received atomic weights, namely, Li 7, Na 23, K 39, Rb 85, Cs 133, and Ag 108, express the relative quantities of each of them which can displace 1 part by weight of hydrogen to unite with 35.5 parts by weight of chlorine. Now it is found by experiment that 7 parts of lithium, 23 parts of sodium, 39 parts of potassium, and 108 parts of silver have substantially the same specific heat as one another; so that 7 parts of lithium and 108 parts of silver, for instance, absorb or evolve the same amount of heat in undergoing the same increment or decrement of temperature. The specific heats of the atomic proportions of these four metals, and by analogy of rubidium and cesium also, are moreover substantially identical with the specific heats of the atomic proportions of chlorine, bromine, and iodine, and may be expressed with sufficient accuracy for our present purpose by the number 6.2, in comparison with the specific heat of water taken as the standard of unity. Each of these metals unites with chlorine in but a single definite proportion, to form a chloride expressible by the general formula MCl, derivable from the type HCl; and the specific heats of these several chlorides and of the corresponding bromides and iodides, approximate to the number 12.4, giving a specific heat of 6.2 for each atom in the molecule.

The chlorides of the monad metals, though more or less volatile at high temperatures, are not sufficiently so to allow of their densities in the vaporous state being ascertained by experiment. Their theoretical vapour-densities, however, are assumed to be the halves of their respective atomic weights, and their molecules are accordingly referred to the normal two-volume standard. One or two of these metals, more particularly lithium and sodium, have been made to combine with the organic radicles methyl and ethyl; but the resulting methides and ethides have not been obtained in an isolated condition, and *à fortiori* have not had their vapour-densities determined.

The metals of this group have the common property of forming sulphates which

combine with sulphate of aluminium to produce a highly characteristic class of hydrated double salts, crystallising in octahedrons, and known by the generic name of the *alums*. They are also distinguished by their capability of forming acid and mixed salts of dibasic acids, and incapability of forming basic and mixed salts of monobasic acids, properties, however, which appertain to silver in only a limited degree. The metals potassium, rubidium, and cesium form a definite sub-group, characterised by special properties. They are the most powerfully basylous or oxidisable of all the elements, and the intensity of their basylity increases in the order of their atomic weights. Their hydrates and sulphhydrates are very soluble in water, forming powerfully caustic solutions. Their carbonates also are very deliquescent, soluble, and caustic compounds. Their chlorides are deliquescent and soluble, their sulphates sparingly soluble, and their platino-chlorides and acid-tartrates almost insoluble. Sodium is far less basylous than potassium, and lithium than sodium. The inferior oxidisability of sodium is well shown by its want of action on a strong solution of caustic soda, and by the facility with which it is produced and manipulated in the operations of modern metallurgy. Its hydrate and sulphhydrate resemble those of potassium, but its carbonate is efflorescent, very moderately soluble, and scarcely at all caustic; while carbonate of lithium is almost insoluble, and the phosphate yet more so, like the carbonates and phosphates of the alkali-earth metals. Moreover, while carbonate of potassium is perfectly fixed in the fire, carbonate of sodium loses a small proportion, and carbonate of lithium a considerable proportion of carbonic anhydride; and again, the solution of chloride of lithium, though to a less degree than that of chloride of magnesium, is decomposed during evaporation, with loss of hydrochloric acid. Silver, although distinguished from most of the heavy metals by the perfect neutrality of its soluble salts, differs from the alkali-metals proper in its high specific gravity, its permanence in air, the insolubility of its chloride, &c., and in the indifference of its oxide and sulphide to the action of water. Nevertheless there seems to be a relationship between sodium and silver manifested by the isomorphism of their anhydrous sulphates, and in other ways. Bearing in mind also the general rule that the specific gravities of allied metals increase in the order of their atomic weights, the superior specific gravity of sodium over that of potassium may be taken to indicate its having a latent association with the heavy metals. The triad metals thallium and gold, in addition to their characteristic trichlorides, form protochlorides corresponding in their specific heats, insolubility, and general properties, to the above-mentioned protochloride of silver, whence the metals themselves may be regarded as being at the same time monatomic and triatomic.

GROUP II.—Dyad Metals; namely, glucinum, magnesium, calcium, strontium, barium, zinc, cadmium, and mercury. The metals of this class agree with those last considered in being more or less strongly basylous, but differ from them in a variety of other particulars. Of glucinum very little is really known, but its unascertained properties will be assumed to correspond generally with the known properties of magnesium. With the exception of mercury, which in addition to its normal chloride, or corrosive sublimate, forms an inferior chloride, or calomel, to be left out of consideration for the present, all the members of this group unite with chlorine in a single proportion only. With the atomic weights formerly accorded to those metals, their chlorides would be represented as protochlorides by the general formula MCl corresponding to HCl ; but doubling their respective atomic weights as advocated more particularly by Wurtz and Cannizzaro, their chlorides must be represented as dichlorides, by the general formula $M^{II}Cl_2$ corresponding to OCl_2 , as shown below:

<i>G</i>	4.5	<i>HCl</i>	<i>OCl²</i>	<i>G</i>	9
<i>Mg</i>	12	<i>MgCl</i>	<i>GCl²</i>	<i>Mg</i>	24
<i>Ca</i>	20	<i>CaCl</i>	<i>CaCl²</i>	<i>Ca</i>	40
<i>Sr</i>	43.75	<i>SrCl</i>	<i>SrCl²</i>	<i>Sr</i>	87.5
<i>Ba</i>	68.5	<i>BaCl</i>	<i>BaCl²</i>	<i>Ba</i>	137
<i>Zn</i>	32.5	<i>ZnCl</i>	<i>ZnCl²</i>	<i>Zn</i>	65
<i>Cd</i>	56	<i>CdCl</i>	<i>CdCl²</i>	<i>Cd</i>	112
<i>Hg</i>	100	<i>HgCl</i>	<i>HgCl²</i>	<i>Hg</i>	200

Several metals not belonging to this group form chlorides analogous to those above tabulated, just as the triad metals thallium and gold form protochlorides analogous to protochloride of silver. The disputed formulæ of a few of them are appended for the sake of illustration:—

<i>Cu</i>	31.75	<i>CuCl</i>	<i>CuCl²</i>	<i>Cu</i>	63.5
<i>Sn</i>	59	<i>SnCl</i>	<i>SnCl²</i>	<i>Sn</i>	118
<i>Pb</i>	103.5	<i>PbCl</i>	<i>PbCl²</i>	<i>Pb</i>	207

The general principles on which the determination of atomic weights must logically depend, were discussed very fully in a previous article (*vide* ATOMIC WEIGHTS), which it may be observed was necessarily written long before the date of its publication. It was therein stated, that although in the author's opinion, the arguments in favour of doubling the atomic weights of the metals now under consideration, were not at that time sufficiently cogent to warrant the adoption of a hasty change in old established usages, yet that, the proposal being then of very recent introduction, it was not improbable that in course of time the objections to which it was liable would be more or less satisfactorily explained away, while further potential arguments might possibly be adduced in its support. And this is what has since actually taken place; for although the objections to the proposal cannot even now be regarded as altogether overcome, yet the arguments in its favour preponderate so largely as to leave no doubt whatever about the ultimate necessity for its adoption. Before considering *seriatim* the reasons for and against the proposed doubling of the atomic weights of these metals, it may be observed at starting, that, just as there are monatomic, diatomic, and triatomic chlorous elements, so should we expect to have monatomic, diatomic, and triatomic basylous elements or metals. It would, moreover, be extremely strange if while triad and tetrad metals are abundantly met with, there should exist only one or two well-known dyad metals. Again, just as among chlorous elements, the distinction between monatomic and triatomic atoms was recognised long before the distinction between monatomic and diatomic atoms, so is it natural that among basylous elements also, the distinction between monatomic and diatomic metals now proposed for adoption, should not be established until long after the distinction between monad and triad metals had been all but universally acknowledged.

a. Atomic Heat.—If we represent the chlorides tabulated above, as dichlorides, we find that the proportions of metal combined with two atoms of chlorine in their respective molecules have their specific heats expressed by the number 6.2, just as have the several proportions of metal united with one atom of chlorine in undisputed protochlorides, and the several proportions of metal united with three atoms of chlorine in undisputed trichlorides. But if we continue to regard the chlorides in question as protochlorides, the proportions of metal contained in their respective molecules will have only half the specific heat of the proportions of metal contained in the molecules of undisputed proto- and trichlorides. In other words, with the doubled weights and formulae, the atoms of this group of metals will have the same specific heats, whereas with the old atomic weights they will have only half the specific heats, of the atoms of chlorous dyads, such as sulphur and selenium; of chlorous and basylous monads, such as bromine, iodine, sodium, and silver; and of chlorous and basylous triads, such as phosphorus, arsenic, thallium, and gold. Moreover the specific heats of their respective chlorides, &c., written as dichlorides, will agree with the specific heats of undisputed proto- and trichlorides in this particular, that, divided by the number of atoms in the molecule, they will all yield the constant 6.2. Thus the ascertained specific heat of corrosive sublimate HgCl_2 ($200 + 35.5 \times 2$) is 18.67, which divided by 3, gives the quotient 6.22.

Objection.—The argument from atomic heat is admitted to have great force; though hardly sufficient to be absolutely decisive of the question, inasmuch as the atomic heats of the non-metals, boron, carbon, and silicon, are not under any circumstances more than half as great as the atomic heats of their metallic congeners. It being therefore impossible to accord the same specific heats to the atoms of all the elements, it is quite conceivable that the atomic heat of certain metals should differ from the atomic heat of the remainder, that magnesium and mercury, for instance, should have only half the atomic heat of sodium and silver. Then the molecule of chloride of mercury HgCl , for instance, would have the specific heat of its constituent atoms, $3.1 + 6.2 = 9.3$; while the molecule of chloride of silver AgCl , would have the specific heat of its constituent atoms, $6.2 + 6.2 = 12.4$.

B. Molecular Volume.—Mercuric chloride and mercuric ethide, if represented as dyadic by the formulae HgCl_2 and HgEt_2 respectively, have the same molecular volume as the corresponding monadic compounds, hydric chloride HCl , and hydric ethide HEt , respectively, and as the corresponding triadic compounds, arsenic chloride AsCl_3 , and arsenic ethide AsEt_3 respectively. The gaseous volumes of zinc-chloride and stannous chloride have not been ascertained, but the gaseous volumes of their corresponding ethides and methides agree with the ethide and methide of mercury, in the circumstance of their respective vapour-densities being the halves of their atomic weights, when they are represented as dyadic compounds, thus:

2 vols.
 HCl
 HEt
 EtCl

2 vols.
 HgCl_2
 HgEt_2
 ZnEt_2
 SnEt_2

2 vols.
 AsCl_3
 AsEt_3
 $\text{B}^{\text{III}}\text{Cl}_3$
 $\text{B}^{\text{III}}\text{Et}_3$

In other words, the volatile chlorides and ethides of these metals, if represented as dyadic, will have the same molecular volume, whereas if represented as monadic they will have only half the molecular volume of undisputed protochlorides and trichlorides, protethides and triethides, &c.

Objection.—The above argument from molecular volume is considered to have rather less weight than that from atomic heat: for by according to chloride of mercury and its congeners the formulæ which bring their molecular volumes into accordance with the molecular volumes of chloride of hydrogen, chloride of oxygen, &c., we are forced to accord to the metals themselves, molecular volumes which are discordant with the molecular volumes of the elements, hydrogen and oxygen, &c., thus:

2 vols.	2 vols.	2 vols.
HCl	H ² O"	Cl ² Hg"
HEt	Et ² O"	Et ² Hg"
EtCl	Cl ² S"	Et ² Cd"
HH	OO	HgHg
ClCl	SS	CdCd
BrBr	SeSe	ZnZn
		} 2 vols.
		} 4 vols.

In other words, the proportions of mercury, of cadmium, and by analogy of zinc, which combine with two atoms of chlorine, or ethyl, or methyl, have double the gaseous volume of the proportion of hydrogen which combines with one atom of chlorine, or ethyl, or methyl, and consequently double the volume of the proportions of oxygen and sulphur respectively which combine with two atoms, and of the proportion of nitrogen which combines with three atoms of chlorine, or ethyl, or methyl. But just as the diatomic chlorous elements, oxygen and sulphur, have the same gaseous volume as, and not double the volume of, the monatomic chlorous elements, chlorine and bromine, so should we expect the diatomic basylous elements, mercury and cadmium, to have the same volume as, and not double the volume of, the monatomic basylous metalloid, hydrogen. This objection has been partly met by comparing the molecules of mercury, cadmium, &c., not with the molecules of free oxygen, free sulphur, &c., which are divisible in the act of combination, but with the molecules of the diatomic compound radicles carbonic oxide, sulphurous anhydride, ethylene, &c., which are indivisible; thus:—

2 vols.	2 vols.	2 vols.
H ²	Hg"	O"Cl ²
Cl ²	Cd"	S"Cl ²
O ²	(CO)"	Hg"Cl ²
S ²	(SO ²)"	Cd"Cl ²
Se ²	(C ² H ⁴)"	(CO)"Cl ²
N ²	(C ² H ⁴)"	(C ² H ⁴)"Cl ²

Whatever value may be accorded to this explanation, however, the experimental discordance undoubtedly remains, that the atomic proportions of the dyadic basylous mercury and cadmium, have double the volume of the dyadic chloroids oxygen and sulphur.

γ. Double Salts.—The characteristic property of a dyad element is its capability, when united with one and the same monatomic radicle, of parting with that radicle by two successive substitutions, and of thereby uniting with two distinct monatomic radicles. Now this property of combining with two different radicles is certainly very well exemplified by the class of metals we are at present considering, as shown in the list of compounds tabulated below, which might be largely extended:

(HgCl) ²	Mercury, dichloride	Hg"Cl ²
HgCl.HgEt	chlor-ethide	Hg"ClEt
(HgEt) ²	diethide	Hg"Et ²
HgEt.HgMe?	etho-methide	Hg"EtMe?
ZnEt.ZnI	Zinc iodo-ethide	Zn"EtI
CaCl.CaClO	Bleaching powder	Ca"Cl ² O
SrNO ² .SrC ² H ³ O ²	Strontium acetato-nitrate	Sr".NO ² .C ² H ³ O ²
BaNO ² .BaC ² H ³ O ²	Barium acetato-nitrate	Ba".NO ² .C ² H ³ O ²
CuHO.CuF	Copper, fluo-hydrate	Cu".HO.F
PbHO.PbNO ²	Lead, hydrato-nitrate	Pb".HO.NO ²
PbHO.PbC ² H ³ O ²	hydrato-acetate	Pb".HO.C ² H ³ O ²

The greater number of these double compounds possess a moderate degree of stability, while some of them, as the double halogen ethides and methides, are among the most definite and stable of metallic salts. The relation of the organic compounds of mercury and arsenic to one another is evidently parallel to that of alcohol and ether to the ethylamines, as shown below:

Triads.		Dyads.		Monads.	
H ⁺ N	Cl ⁺ As	H ⁺ O	C ⁺ Hg	HCl	ClNa
EtH ⁺ N	EtCl ⁺ As	EtHO	EtClHg	EtCl	EtNa
Et ⁺ HN	Et ⁺ ClAs	Et ⁺ O	Et ⁺ Hg		
Et ⁺ N	Et ⁺ As				

Again, just as in alcohol, the basylous radicles, hydrogen and ethyl, are held together by diatomic oxygen, so in the hydrate-nitrate of lead, the two chlorous radicles are held together by diatomic lead (Williamson, Chem. Soc. J. xvii. 211). Accordingly, if in alcohol we replace diatomic oxygen by monatomic chlorine, we get two distinct chlorides, thus:

And similarly, if in our lead-salt we replace diatomic lead by monatomic silver, we get two distinct argentides, thus:

Objections.—The force of this argument is much diminished by remembering that certain undoubted monatomic elements and groupings have the property, though to a limited extent, of combining with two distinct monatomic radicles. Chlor-ethide of mercury, for instance, Hg^+EtCl , may be written $(\text{Hg}^+)\text{EtCl}$, and compared with iodo-nitrate of silver, $(\text{Ag}^+)\text{INO}^+$, argento-chloride of sodium, $(\text{Cl}^+)\text{AgNa}$, hydro-fluoride of potassium, $(\text{K}^+)\text{HK}$, hydro-acetate of potassium, $(2\text{C}^+)\text{H}^+\text{O}^+\text{HK}$, and many similar compounds, in which we have the monatomic elements silver, chlorine, fluorine, as well as monobasic acetic acid, &c., combined with two different monatomic radicles, although, indeed, the stability of these compounds, save and except some of the hydro-fluorides, is of a very feeble character. Moreover, in contrasting the properties of monatomic ethyl and diatomic ethylene, and comparing the undisputed monad metals with the former, and the metals under discussion with the latter, there is one point, at any rate, of some importance in which the comparison does not hold good. The hydrogen of a dibasic acid is found to be replaceable by two different monatomic radicles, and by the same radicle at two successive stages, whereas it is replaceable by a single diatomic radicle only, and that at a single operation. Thus the diatomic radicle ethylene may be substituted for the hydrogen of oxalic acid to form oxalate of ethylene, $(\text{C}^+\text{H}^+)\text{C}^+\text{O}^+$, which is the only derived oxalate of ethylene hitherto known; but with the monatomic radicle ethyl we have acid oxalate of ethyl, $(\text{C}^+\text{H}^+)\text{HC}^+\text{O}^+$, neutral oxalate of ethyl, $(\text{C}^+\text{H}^+)\text{C}^+\text{O}^+$, potassic oxalate of ethyl, $(\text{C}^+\text{H}^+)\text{KC}^+\text{O}^+$, &c. In other words, the monatomic radicle ethyl does, and the diatomic radicle ethylene does not, form acid and double ethers or salts of dibasic acids; and a similar difference of behaviour is manifested by monatomic and diatomic chlorous radicles, such as acetyl $(\text{C}^+\text{H}^+\text{O}^+)$ and oxalyl (C^+O^+) , in their relation to a diacid base such as glycol. Now there certainly does not seem to be any decided difference in this particular between the two groups of metals. One member, at any rate, of the first group—namely, silver—does not or scarcely does, while several of the members of the second group very readily do, form well-defined acid and double salts, as exemplified by the acid oxalate of barium, BaHC^+O^+ , potassic-oxalate of zinc, ZnKC^+O^+ , acid carbonate of magnesium, MgHCO^+ , gay-lussite, CaNaCO^+ , dolomite, MgCaCO^+ , acid sulphate of zinc ZnHSO^+ , glauberite, CaNaSO^+ , acid selenite of calcium, CaHSO^+ , &c. &c. Such salts as the sulphovinates of calcium and barium cannot properly be adduced in illustration, because, although for some purposes, sulphovinic acid may be regarded as a double sulphate of ethyl and hydrogen, comparable with acid sulphate of potassium, yet it is in reality a conjugated compound analogous to the sulphamic and sulphophenic acids, for instance, and consequently as much monobasic as the formic, acetic, and nitric acids themselves.

It cannot, however, be contended in any way that the property of forming acid and double salts with dibasic acids is incompatible with the diatomic character of the metals forming them; for, indeed, there is no sufficient reason why the atom of a dyad metal should not bind together two atoms of dibasic sulphuric acid, for instance, just as we believe the diatomic radicle sulphuryl binds together two atoms of dihydric water, thus:—

The utmost that can be said is, that the difference of properties exhibited by ethylene and ethyl in their behaviour with dibasic acids, is not paralleled by a corresponding difference of properties manifested under similar circumstances by members of the two groups of metals.

3. Basic salts.—A well-marked distinction between monatomic and polyatomic radicles, which has been pointed out more especially by Wurtz, results from the special tendency which the oxides of polyatomic, and particularly diatomic radicles have, to produce basic and anhydro-salts; or, as Wurtz expresses it, from the power which they have of accumulating in combination, and of thereby forming compounds* containing multiple radicles, and belonging to types of greater and greater complexity. Thus we are acquainted with potassic monochromate, $\text{K}^2\text{O}(\text{CrO}^2\text{O})$, potassic anhydrodichromate, $\text{K}^2\text{O}(\text{CrO}^2\text{O})^2$, and potassic anhydro-trichromate, $\text{K}^2\text{O}(\text{CrO}^2\text{O})^3$. Again, we have monethylenic glycol, $(\text{C}^2\text{H}^4\text{O})\cdot\text{H}^2\text{O}$, diethylenic glycol, $(\text{C}^2\text{H}^4\text{O})^2\cdot\text{H}^2\text{O}$, triethylenic glycol, $(\text{C}^2\text{H}^4\text{O})^3\cdot\text{H}^2\text{O}$, and tetrethylenic glycol, $(\text{C}^2\text{H}^4\text{O})^4\cdot\text{H}^2\text{O}$, &c. This distinction, unlike those hitherto considered, is simply a matter of observation. We observe that diatomic oxides do, and monatomic oxides do not, as a general rule, accumulate in the manner above exemplified; but we see no reason why such a difference of behaviour should result from the different atomicities of the radicles. On this account therefore, that it is based on a difference of behaviour not directly deducible from difference of constitution, we can scarcely attach so much importance to this last distinction as to those which have been previously discussed. At the same time, the different habit of monatomic and diatomic radicles in this particular is very well marked. We are acquainted, for instance, with super-basic hydrates, chlorides, and acetates of ethylene, but with no super-basic hydrates, chlorides, or acetates of ethyl. The question consequently arises, whether a similar difference subsists between the alleged diatomic and the undisputed monatomic metals; and the answer, that such a difference does exist, is certainly, so far as it goes, in favour of the diatomicity of the metals now under consideration. Thus we can parallel some of the basic hydrates, chlorides, acetates, &c. of ethylene by similar compounds of calcium, magnesium, zinc, lead, copper, &c., but not by any compounds of the undoubtedly monad metals. We have, for example, Schaffner's hydrate of lead, $\text{H}^2\text{O}(\text{PbO})^2$; Payen's hydrate of lead, $\text{H}^2\text{O}(\text{PbO})^3$; Mendipite, $\text{PbCl}_2(\text{PbO})^2$; Atacamite, $\text{CuCl}_2(\text{CuO})^3$; Schindler's oxychloride of zinc, $\text{ZnCl}_2(\text{ZnO})^2\cdot 2\text{H}^2\text{O}$; Rose's oxychloride of calcium, $\text{CaCl}_2(\text{CaO})^3\cdot 16\text{H}^2\text{O}$; hydromagnesite, $(\text{MgCO}^2\cdot\text{H}^2\text{O})\cdot\text{MgH}^2\text{O}^2$; dibasic acetate of copper, $\text{C}^4\text{H}^4\text{CuO}^4\cdot\text{CuO}\cdot 3\text{H}^2\text{O}$; dibasic acetate of lead, $\text{C}^4\text{H}^4\text{PbO}^4\cdot\text{PbO}\cdot 3\text{H}^2\text{O}$; tribasic acetate of copper, $\text{C}^4\text{H}^4\text{CuO}^4(\text{CuO})^2$; tribasic acetate of lead, $\text{C}^4\text{H}^4\text{PbO}^4(\text{PbO})^2\cdot 3\text{H}^2\text{O}$; Mitscherlich's dibasic nitrate of mercury, $\text{Hg}^2\text{N}^2\text{O}^4\cdot\text{HgO}\cdot 2\text{H}^2\text{O}$, &c. &c. This is perhaps a suitable place for referring to an observation of Wurtz, to the effect that, by representing the metals of this group as diatomic, we are able to express the simple molecules of their several salts, with entire instead of with half atoms of water of crystallisation, as illustrated by the following among many other examples: acetate of copper, $\text{C}^4\text{H}^4\text{CuO}^4\cdot\text{H}^2\text{O}$; acetate of lead, $\text{C}^4\text{H}^4\text{PbO}^4\cdot 3\text{H}^2\text{O}$; perchlorate of lead, $\text{PbClO}^4\cdot 3\text{H}^2\text{O}$; nitrate of copper, $\text{CuN}^2\text{O}^4\cdot 3\text{H}^2\text{O}$; chloride of nickel, $\text{NiCl}^2\cdot 9\text{H}^2\text{O}$, &c.

Objections.—It is contended that the property of accumulating in combination is not necessarily but only accidentally associated with polyatomicity, and that, just as the acetic and iodic anhydrides* form anhydro-salts, such as $(\text{C}^2\text{H}^4\text{KO})^2\cdot\text{C}^2\text{H}^4\text{O}^2$ and $\text{KIO}^4\cdot\text{I}^2\text{O}^4$, without prejudice to their monatomicity, so may the plumbic and cupric base-oxides form basic salts without prejudice to their monatomicity. From several considerations, however, the existence of a diacetic acid $\text{C}^4\text{H}^4\text{O}^4$, and a trihydric iodic acid, H^3IO^4 , seems not improbable; and if so, the anhydro-acetates and anhydro-iodates may be associated in reality with the polybasic forms of their respective acids. As for the argument from water of hydration, taken by itself, it certainly cannot lay claim to any great weight, since there is no more obvious reason why one atom of water should not combine with two atoms of salt, H^2O with $(\text{C}^2\text{H}^4\text{CuO})^2$ for instance, than there is why one atom of salt should be able to combine with two or three atoms of water.

But although the arguments in favour of regarding the zinc-calcic group of metals as dyadic, when taken separately, are open to the objections above pointed out, yet taken altogether, they seem to present so great a preponderance of evidence in support of the proposal, as to render its adoption almost a matter of necessity. Accepting this conclusion, then, as inevitable, and according to the above metals the doubles of their previously received atomic weights, we are at once struck by the very obvious paral-

lithium subsisting between them and the already considered monad metals, as shown below:—

Li' 7	G" 9		
Na' 23	Mg" 24	K' 39	Ca" 40
—	Zn" 65	Rb' 85	Sr" 87.5
Ag' 108	Cd" 112	Cs' 133	Ba" 137
	Hg" 200		

The metals of the alkaline-earth sub-group, namely, calcium, strontium, and barium, are scarcely less basyious or oxydisable than those of the alkalis, and the degree of their basyility also increases in the order of their atomic weights. Their hydrates and sulphhydrates, like those of the alkali-metals, are soluble in water, forming caustic solutions which absorb carbonic anhydride with great avidity, to form, however, insoluble carbonates; and their sulphates are likewise insoluble. Among the members of the other sub-group, the manifestation of metallic properties, as popularly understood, rather than of basyious characters, increases in the order of their atomic weights; and accordingly we may regard the upper members of each sub-group as exhibiting a very general form, and the lower members as exhibiting highly specialised forms of the metallic character, and may figure the difference to ourselves in some such diagram as the following:—

Glucinum	
Magnesium	Calcium
Zinc	Strontium
Cadmium	Barium
Mercury	

The metals of the less basyious or more reguline sub-group are distinguished by their volatility, which increases in the order of their several atomic weights. The hydrates of these metals are insoluble in water, and only those of glucinum and magnesium manifest much affinity for carbonic anhydride. The sulphides of zinc, cadmium, and mercury are insoluble permanent precipitates, while that of magnesium also appears to be insoluble in, though readily decomposable by water. Their sulphates, unlike those of the more basyious dyads, are all soluble in water, with the exception of sulphate of mercury, which is decomposed thereby into sulphuric acid and a basic salt. In many points of its behaviour, magnesium presents a general resemblance to calcium, and was at one time classified with the alkaline-earth metals.

In addition to corrosive sublimate, HgCl_2 , mercury forms an inferior chloride, or calomel, whose molecule may be represented by the formula HgCl , corresponding to that of proto-chloride of silver, AgCl , or by the formula Hg^2Cl^2 , corresponding to that of subchloride of sulphur S^2Cl^2 ; and the selection of one or other of these expressions will of course determine the entire series of formulas to be accorded to the entire series of mercurous salts. The formula HgCl , by which calomel is represented as a proto-chloride of mercurousum, is recommended by its superior simplicity, by the ready susceptibility of mercurous salts to double decomposition without change of type, by the resemblance of calomel to the insoluble monad chlorides of silver, gold, &c., and by the determination of its vapour-density, which is found to be $\frac{200 + 35.5}{2} = 117.75$; so that two volumes of calomel vapour, HgCl , contain one volume of chlorine, just as two volumes of hydrochloric acid, HCl , contain one volume of chlorine. On the other hand, the formula Hg^2Cl^2 is recommended by its consistency with the law of even numbers, which declares that a dyad element can never unite with an uneven number of monad atoms, and with the frequent spontaneous decomposition of mercurous salts into mercuric salts and mercury, $\text{Hg}^2\text{Cl}^2 = \text{HgCl}_2 + \text{Hg}$. Moreover, the existence of several basic mercurous compounds is opposed to the representation of normal mercurous compounds as proto-salts; while the discordance in molecular volume between calomel and subchloride of sulphur, as revealed by the determination of their vapour-densities ($\text{S}^2\text{Cl}^2 = 2$ vols., while $\text{Hg}^2\text{Cl}^2 = 4$ vols.), may be explained by supposing that the vapour of calomel, like that of many other salts, undergoes what is known as dissociation (i. 469; ii. 816) into two volumes of mercuric chloride, HgCl_2 , and two volumes of mercury, Hg . This supposition is to some extent warranted by the observation that calomel vapour amalgamates gold leaf, and that corrosive sublimate may be detected in resublimed calomel (Chem. Soc. J. xvii. 421).

GROUP III. Triad Metals.—Classifying the metals according to their maximum atomicities, there are four triad metals properly so called, namely, aluminium, thallium, indium, and gold; for the trichlorides of arsenic, antimony, and bismuth must be regarded as the inferior chlorides of pentad, just as the protochlorides of thallium and gold are the inferior chlorides of triad elements. The formula for thallic chloride, $TlCl_3$, and the atomic weight for thallium, 203, have not at any time been disputed. Auric chloride was formerly represented as a sesquichloride by the formula Au_2Cl_3 , the atomic weight of gold being taken as 98; but it is now always represented as a trichloride by the formula $AuCl_3$, the atomic weight of the metal being fixed at 196. The old sesquiatomic formula for aluminic chloride, Al_2Cl_3 , in accordance with which the atomic weight of aluminium was taken as 13.75, cannot now be defended on any rational grounds. It is admitted on all hands that the smallest proportion of aluminium found to exist in any definite compound is 27.5 parts, and that this proportion is indivisible or atomic throughout all the reactions which aluminic compounds undergo. Evidently, therefore, it ought to be represented as indivisible or atomic by the symbol Al''' , and not as dipartite by the symbol Al^2 . Regarded as triadic, with the atomic weights 27.5, 203, and 196.5 respectively, it is found that the specific heats of the atoms of aluminium, thallium and gold approximate to the number 6.2, and are accordingly identical with the specific heats of the atoms of monad metals, such as sodium and silver, of dyad metals such as magnesium and mercury, of tetrad metals such as tin and lead, and of pentad metals such as arsenic and antimony, &c. The trichlorides of thallium and gold are decomposed by heat, with evolution of chlorine; but aluminic chloride volatilises unchanged, and its vapour-density has been found by Deville to accord, not with the molecular formula $AuCl_3$, but with the more complex expression Al_2Cl_6 . But from experiments by Mr. Buckton and the author of this article, it appears that the vapour-densities of aluminic methyl and ethyl accord unmistakably with the molecular formulæ $AlMe^3$ and $AlEt^3$ respectively. Aluminium-methyl certainly is, and aluminic chloride not improbably may be, a body of the same class as formic acid, acetic acid, boric methide, sulphur, selenium, &c., whose vapours require to be heated very far above the boiling points of the several liquids before acquiring their normal molecular volumes. Thus, at 220° and all superior temperatures, the corrected vapour-density of aluminium-methyl is perfectly constant, and accords with the formula $AlMe^3$; but below 220° its corrected density increases at a very rapid rate, so as to become nearly doubled at 130°, which high density would of course accord approximatively with the formula Al_2Me^6 . Bearing in mind, however, the rule deducible from the separate experiments of Deville and Cahours, that the molecular formula of a body is to be calculated from its permanent or ultimate, and not from its variable or initial vapour-density, and having regard also to the ascertained behaviour of the vapour of aluminic methide, the only observed vapour-density of aluminic chloride cannot, in the author's opinion, be regarded as affording decisive evidence in favour of the formula Al_2Cl_6 . If this latter formula were established, aluminium would have to be regarded as a tetrad, and

its chloride would be represented by the constitutional formula $\begin{array}{c} AlCl_3 \\ | \\ AlCl_3 \end{array}$, the two quadri-

valent atoms of aluminium forming a sexvalent group like the two atoms of carbon in the molecule of hydride of ethyl C^2H^4 . On the same supposition the alums would be represented by such formulæ as $K^2(Al^2)^2(SO^4)^4$ derived from $4H^2SO^4$, whereas if aluminium be regarded as trivalent, they will be represented by simple formulæ like $KAl'''(SO^4)^3$ derived from $2H^2SO^4$. But there is nothing in the composition or the chemical character of these salts, or indeed of any other aluminium compounds, to enable us to decide positively one way or the other. The triadic character of aluminium receives, however, some support from the circumstance that certain aluminic compounds present a marked resemblance in composition and properties to similar undoubted triatomic compounds of other elements, as of boron and antimony, for instance. Boron would seem to stand to aluminium in much the same relation as that in which lithium stands to sodium, and glucinum to magnesium. In each pair of elements the basility of the second is superior to that of the first term; while the monadic are more basyious than the corresponding dyadic, and these again more basyious than the corresponding triadic elements. Boric and aluminic hydrates alike act either as feeble acids or feeble bases. The isomorphous borate and aluminate of magnesium, or boracite and spinelle, though both subject to a considerable range of composition, are referrible to the similar formulæ MgB^3O^4 and $MgAl^3O^4$, respectively. As before remarked, however, the specific heat of the atom of boron is anomalous.

Thallium would appear to occupy among the triad metals a position similar to that

of mercury among the dyads; but the position of gold in this group, whatever that position may be, is without obvious parallel. In addition to their trichlorides, &c., thallium and gold each form a protochloride and a well-defined series of monad salts. The similarity of several of the monad salts of thallium to the corresponding compounds of potassium is very marked. Thus its chloride produces an insoluble double salt with chloride of platinum; its acid tartrate occurs as a crystalline precipitate; its sulphate forms with sulphate of aluminium a well characterised alum; while its hydrate is readily soluble in water, forming a caustic solution which absorbs carbonic anhydride from the air. On the other hand, protosulphide of thallium, like that of silver, constitutes a dense black precipitate. Again, protochloride of thallium, though more soluble in water, has a general resemblance to chloride of silver, while the protobromides and iodides of the two metals present even a greater degree of similarity. The most stable of the monad salts of gold is the soluble crystalline sodio-sulphide, $\text{AuNaS}_4\text{H}^{20}$. The protoxide is very unstable, and the protochloride is known only as an insoluble residue.

Indium, which was discovered by Reich and Richter in 1863, and is especially characterised by the two indigo-blue bands appearing in its spectrum, is a very soft lustrous metal, permanent in air and water, and having a specific gravity of about 7.2. Its hydrate and carbonate constitute white precipitates, and its sulphide a yellow precipitate insoluble in acetic, but soluble in mineral acids, while its chloride may be obtained as a white crystalline sublimate. Its equivalent weight is 37.8, and its specific heat, according to Bunsen, is 0.057; hence its atomic weight is 3×37.8 or 113.4: for $113.4 \times 0.057 = 6.5$. The formula of its chloride is accordingly InCl^3 , that of its yellow oxide, which is a salifiable base, In^2O^3 , &c. It belongs to the reguline division of the metals, and bears much the same relation to thallium that tin bears to lead.

GROUP IV. Tetrad Metals; including tin, lead, titanium, zirconium, thorium.—These metals are associated with the non-metallic tetrads carbon and silicon, just as the triad elements aluminium and boron are associated with one another. The tetrad elements agree with those of the monad and dyad groups in being divisible into a more especially reguline, and a more especially basylous sub-group, the lower members of each of which possess the respective distinctive characters of the sub-group in their greatest intensity. The relations of the members of the first five groups to one another is shown in the following table:—

Monads.	Dyads.	Triads.	Tetrad	Pentads.
Li 7	Gl 9	Bo 11	C 12	N 14
Na 23	Mg 24	Al 27.5	Si 28	P 31
" ..	Zn 65	" ..	" ..	As 75

Rb 85	Sr 87.5	" ..	Zr 89.5	" ..
Cs 133	Ba 137	" ..	" ..	" ..
			Th 231	

The tetrahydric character of marsh gas has been recognised from almost the earliest days of organic chemistry, but the now received formula CH_4 , in which the carbon is represented as indivisible or atomic, was first introduced by Gerhardt in 1842, instead of the previously employed formula C^2H^4 , in which the carbon was unwarrantably represented as diatomic. The tetratomicity of tin and silicon was first advocated by the author in 1857 and the following years (Phil. Mag. xiii. 434, and xviii. 368; Rep. Brit. Assoc. 1858, p. 68), and was definitively established by the separate researches of Cahours on the stannethyle in 1860 (Ann. Ch. Phys. [3] lviii. 5), and of Friedel and Crafts on the organic compounds of silicon (Bull. Soc. Chim. 1863, p. 174). The tetratomicity of titanium and zirconium follows as a matter of course from the observed vapour-densities of their chlorides, and similarly that of lead from the vapour-density of its ethylide, though it is believed that this is the first occasion on which lead has been definitely classified as a tetratomic element, in association with tin rather than with calcium. The chlorides of carbon, silicon, tin, titanium and zirconium, represented as tetrachlorides by the general formula $\text{M}^{\text{IV}}\text{Cl}_4$, and the ethylides of silicon, tin, and lead, represented by the general formula

$M'''Et^4$, have vapour-densities which are the halves of their respective molecular weights, and accordingly have the same molecular volume as the protochloride of hydrogen HCl , the dichloride of mercury $HgCl^2$, and the triethylide of aluminium $AlEt^3$, &c. Moreover, the chlorine of the chlorides of carbon, silicon, and more especially of tin, is found to be experimentally replaceable at four successive stages. Thus, we have $SnCl^4$, $SnCl^3Et$, $SnCl^2Et^2$, $SnClEt^3$ and $SnEt^4$, corresponding to CCl^4 , CCl^3H , CCl^2H^2 , $CClH^3$, and CH^4 , respectively, and so on. Again with the tetrad atomic weights 118 and 207, the metals tin and lead have the normal atomic heat which is expressed more or less closely by the number 6.2. The specific heats of the other metals of this group have not been ascertained, but the specific heats of carbon and silicon among the tetrad elements, like that of boron among the triad elements, must, according to our present imperfect knowledge, be regarded as exceptional or anomalous.

Tetrachloride of tin is a colourless fuming liquid, which combines with water to form a series of crystalline soluble salts. Tetrachloride of lead is known only in the form of hydrated crystals. It is made by treating peroxide of lead, PbO^2 , with cold aqueous hydrochloric acid, when solution takes place without effervescence, and on evaporation in vacuo, crystals of the tetrachloride separate out, together with much dichloride of lead. The solutions of the tetrachlorides of tin and lead are decomposed by alkalis, with precipitation of the respective peroxides, and by sulphuretted hydrogen, with precipitation of the respective persulphides, the former of a pale yellow, the latter of an orange-red colour. The dichlorides of tin and lead, which have been incidentally referred to when discussing the dyad metals, are readily fusible, volatile solids, whose solutions, like those of the tetrachlorides, are decomposed by alkalis, with precipitation of their respective protoxides, and by sulphuretted hydrogen, with precipitation of their respective protosulphides, the former of a dark brown, and the latter of a black colour. It may be here observed that the property of forming insoluble sulphides, not readily decomposed by water, constitutes a useful distinguishing character between the reguline and alkaligenous sub-groups of metals belonging to each of the primary groups, this property being manifested by silver, zinc, cadmium, mercury, thallium, tin, lead, arsenic, antimony and bismuth, but not by potassium, caesium, rubidium, calcium, strontium, barium, titanium, zirconium and thorium, or yet by the metals yttrium, cerium, lanthanum, and didymium, to which we shall presently refer more particularly. Many of the dyad salts of reguline lead, however, present a marked resemblance in properties to the similar salts of the alkali-earth metals, and are frequently isomorphous with them, just as the monad salts of reguline thallium correspond with the similar salts of potassium. On the other hand, an almost special characteristic of lead, and one strongly corroborative of its polyatomicity, consists in its very marked tendency to form double and superbasic salts with monatomic radicles. Lead differs also from its congener, tin, in the greater degree of its basylity, or power of neutralising even feeble acids; while a further difference between them results from the superior stability of the di-salts over the tetra-salts of the one metal, and of the tetra-salts over the di-salts of the other.

The less reguline sub-group of tetrad metals, namely, titanium, zirconium and thorium, are associated with silicon and tin by the isomorphism of rutile, TiO^2 , and artificial thorina, ThO^2 , with native tinstone SnO^2 (Nordenskiöld and Chydenius, Pogg. Ann. cx. 642), and by the vapour-densities of titanic and zirconic chlorides, $TiCl^4$ and $ZrCl^4$, corresponding with that of stannic chloride, $SnCl^4$. The sulphides of titanium, zirconium and thorium are not producible in the moist way. Their oxides are hard crystalline bodies unattacked by ordinary acids, save the hydrofluoric. Their hydrates occur as white gelatinous precipitates, which dissolve readily in acids, to form more or less definite salts. Just as the hydrates of the dyad alkaline-earth metals, $M''H^2O^2$, are less soluble and basylous than those of the monad alkali-metals, so should we expect the hydrates of the unrecognized triad earth-metals, $M'''H^3O^3$, to be less soluble and basylous even than those of the dyads, and the hydrates of the non-reguline tetrad metals, $M''''H^4O^4$ or $M'''H^2O^4$ ($= M''H^2O^4 - H^2O$), to be still less so. In other words, we should be prepared to find, in the sub-group of tetrad metals we are now considering, but a very inferior degree of basylity, more especially in the superior members of the sub-group, seeing that the degree of basylity habitually increases in the order of the atomic weights of the consecutive metals. We accordingly find that the characters of hydrated titania are fully as much acid as alkaline, though we are nevertheless acquainted with sulphates, nitrates, phosphates and even a potassio-carbonate of titanium. But the basylity of zirconia is far better marked. Its silicate constitutes zircon; its carbonate is formed by precipitation; its sulphate is a soluble crystalline salt; while its potassio-sulphate is thrown down as a crystalline precipitate on mixing solutions of the separate sulphates of potassium and zirconium. Thorium forms a large number of well-defined

salts, including a potassio-sulphate corresponding to that of zirconium in its character and mode of formation. Moreover, hydrated thorina is sufficiently basyious to expel ammonia from sal-ammoniac, and to absorb carbonic anhydride from the atmosphere.

The metals yttrium, erbium, cerium, lanthanum, and didymium possess the following properties in common with one another and with thorium:—Their hydrides constitute gelatinous precipitates, which expel ammonia from sal-ammoniac solution, and absorb carbonic anhydride from the atmosphere. Their sulphides are not producible in the moist way, and their sulphates are precipitated by sulphate of potassium in the form of crystalline double salts. The equivalent weights of these four metals, which replace 1 pt. of hydrogen to unite with 35.5 pts. of chlorine, are Y 32, Er = 56.3, La 46, and Di 48, but what their atomic weights are is altogether undecided. In the present state of knowledge, their extreme basyility cannot any longer be regarded inconsistent with their di-, tri-, or even tetraatomicity, and there are some points in the behaviour of didymium, at any rate, which are suggestive of its being a triad pent. Cerium is distinguished from lanthanum and didymium, as well as from Y, by the facility with which it forms a superior and feebly salifiable oxide.

Pentad Metals.—These are six in number, namely arsenic, antimony, bismuth, vanadium, niobium, and tantalum; they are associated with the non-metallic nitrogen and phosphorus, just as the tetrad metals tin and lead are associated with the non-metallic tetrads carbon and silicon. Although the pentatomicity of the first four of these elements is very well established, as shown by the phosphoric and arsenic acids, for instance, and their corresponding chlorides and oxides, as formulated below, yet it must be admitted that their more general and characteristic behaviour is triadic:

In some cases, moreover, these elements form monad compounds. Thus, Griess has shown that, in a variety of organic bodies, a single atom of nitrogen may be substituted either for 1 or for 3 atoms of hydrogen. Phosphorus and its associated metals were formerly represented by atomic weights, the halves of those now universally adopted, and it is only within a very few years that the habit of writing the antimonious and bismuthous chlorides as sesquichlorides by the formulæ $\text{Sb}^{\text{Sb}}\text{Cl}^{\text{Cl}}$ and $\text{Bi}^{\text{Bi}}\text{Cl}^{\text{Cl}}$, respectively, has been completely abandoned; nor indeed is it very long since chloride of bismuth was frequently represented as a protochloride by the formula BiCl . It is only, however, with the atomic weights now employed, namely, P 31, As 75, Sb 122, and Bi 210, that the atoms of the four elements have approximately the standard specific heat of 6.2. The specific gravity of nitrogen gas being identical with its atomic weight, or with the half of its molecular weight, the two-volume molecule of nitrogen is represented by the expression $\text{N}^{\text{N}}\text{N}^{\text{N}}$, just as that of oxygen is represented by $\text{O}^{\text{O}}\text{O}^{\text{O}}$, and that of hydrogen by $\text{H}^{\text{H}}\text{H}^{\text{H}}$. Deville, however, has shown that the vapour-densities of phosphorus and arsenic are the doubles of their respective atomic weights, and that these densities when corrected, are unalterable by any increase of temperature, so that the two-volume molecules of phosphorus and arsenic have to be represented by the expressions P^{P} and As^{As} . Williamson has very plausibly suggested that, while the molecule of nitrogen may be regarded as ammonia, $\text{N}^{\text{N}}\text{H}^{\text{H}}$, in which the three atoms of monatomic hydrogen are replaced by one atom of triatomic nitrogen, $\text{N}^{\text{N}}\text{N}^{\text{N}}$, the molecules of phosphorus and arsenic may be regarded as phosphine and arsine, $\text{P}^{\text{P}}\text{H}^{\text{H}}$ and $\text{As}^{\text{As}}\text{H}^{\text{H}}$, in which the three atoms of monatomic hydrogen are replaced by three atoms of monatomic phosphorus and monatomic arsenic respectively, $\text{P}^{\text{P}}\text{P}^{\text{P}}$ and $\text{As}^{\text{As}}\text{As}^{\text{As}}$. They may also be represented by formulæ in which each of the atoms of phosphorus or arsenic

is pentatomic, e.g. $\begin{array}{c} \text{P} \equiv \text{P} \\ || \\ \text{P} \equiv \text{P} \end{array}$. Except that bismuth does not form a trihydride, the

volatile trihydrides, triethylides, and trichlorides of these five elements all form two-volume molecules, while the hydrogen, ethyl, and chlorine of the respective compounds are readily replaceable in thirds at three successive stages. The majority of the pentad compounds dissociate or decompose at or below their boiling points; but the molecules of nitric acid $\text{N}^{\text{N}}\text{H}^{\text{H}}\text{O}^{\text{O}}$, oxychloride of phosphorus $\text{P}^{\text{P}}\text{Cl}^{\text{Cl}}\text{O}^{\text{O}}$, oxy-ethylstibine $\text{Sb}^{\text{Sb}}\text{Et}^{\text{Et}}\text{O}^{\text{O}}$, &c. &c., have vapour-densities which are the halves of their atomic weights, and accordingly correspond with the normal two-volume standard. Arsenic, antimony, and bismuth differ from the majority of the metals in being destitute of malleability or tenacity, and are therefore very commonly described as brittle or semi-metals. Their reguline character is, however, very well marked, and their sulphides

are easily formed by precipitation. The permanently reguline habit of arsenic, however, is less decided than that of its congeners; for finely powdered arsenic oxides readily in moist or heated air, and its precipitated sulphide is slowly decomposed by boiling with water. All three metals manifest both acid and basic properties, the former being shown most strikingly by arsenic and the latter by bismuth.

Vanadium was formerly regarded as a hexad analogous to chromium. Berzelius indeed obtained three oxides to which he assigned the formulæ VO , VO^2 and VO^3 [$V = 68.5$; $O = 8$]. The highest of these, namely, vanadic oxide, or anhydride, exhibits considerable resemblance to chromic anhydride CrO_3 , the two oxides being red or orange-coloured, non-fusible, crystalline solids, soluble in water, decomposable by heat, and uniting with basic oxides to form very stable orange-coloured salts, for example the native chromate and vanadate of lead, and the very characteristic bichromate or anhydro-chromate of potassium, and the corresponding vanadate. On the other hand, vanadium was known to form compounds isomorphous with analogous compounds of the phosphorus and arsenic group, vanadinite for example, which is a compound of vanadate and chloride of lead, being isomorphous with apatite, pyromorphite and mimetite, minerals consisting respectively of phosphatochloride of calcium, phosphatochloride of lead and arsenatochloride of lead. This anomaly gave rise to the suspicion that vanadium might belong to the phosphorus group of elements, and this view has been completely established by the experiments of Roscoe, who has shown that the supposed metallic vanadium of Berzelius was really an oxide, and that the quantities of oxygen in this and the three higher oxides above mentioned are in the proportion of the numbers 2, 3, 4 and 5, these oxides being in fact represented by the formulæ V_2O_3 , V_2O_4 , V_2O_5 , V_2O_6 , and the metal vanadium, which Roscoe has isolated by reduction of the chloride with hydrogen, having the atomic weight 51. Roscoe has also shown that vanadic anhydride V_2O_5 forms with metallic oxides three classes of salts, viz. orthovanadates $3M_2O.V_2O_5$, pyrovanadates $2M_2O.V_2O_5$, and metavanadates $M_2O.V_2O_5$, analogous to the three well-known classes of phosphates. He has also obtained the three chlorides VCl_2 , VCl_3 , VCl_4 , and several oxychlorides, one of them, $VOCl_3$, being analogous to phosphorous oxychloride $POCl_3$. The formulæ of the di- and tetra-chlorides, which are confirmed by the vapour-densities of the respective compounds, show that vanadium exhibits an exception to the general rule that the variation of atomicity or combining capacity in an element takes place by pairs of units; in other words, they show that this element is both triad and pentad.

Tantalum and Niobium differ from the pentad metals above noticed in being solely pentadic, and not forming any triadic compounds like PCl_3 , As_2O_3 , &c.

Tantalum, discovered in 1802 by Ekeberg in tantalite and yttratanalite from Finland, was formerly regarded, in accordance with the experiments of H. Rose, as a tetrad, forming the chloride $TaCl_4$ and the oxide TaO_2 [$Ta = 138$]; but from the observations of Marignac on the isomorphism of the fluorantates and fluoniobates, and the vapour-density 12.42 of the chloride, as determined by Deville and Troost, it appears that the true formula of the chloride is $TaCl_5$ and that of tantalum oxide or anhydride Ta_2O_5 [$Ta = 182$]. There is also a lower oxide TaO_3 . (See vol. v. pp. 662-669.)

Niobium or Columbium, discovered by Hatchett in 1801 in American columbite, was pronounced by Wollaston in 1809 to be identical with Ekeberg's tantalum. But the more exact experiments of H. Rose have shown that the two metals are distinct. They occur together in almost all tantalites and columbites; but some tantalites, as that of Kimito in Finland, are free from niobium, and some of the Greenland columbites contain only the latter metal unmixed with tantalum. The two metals are extremely difficult to separate, and it was their simultaneous occurrence which vitiated the early analyses of the minerals containing them. Niobium forms a pentachloride $NbCl_5$, and an oxychloride $NbOCl_3$ [atomic weight of niobium = 94], the formulæ of which are established by their analyses and vapour-densities. Niobic oxide or anhydride Nb_2O_5 unites with basic oxides forming the niobates. The native columbites are niobates of iron and manganese, $(FeO; MnO)Nb_2O_5$. According to Delafontaine there are also two lower oxides NbO and NbO_2 , but their constitution is not well established. (See vol. iv. pp. 48-58.)

GROUP VI. Hexad Metals.—The metals characteristic of this group—namely tellurium, molybdenum, and tungsten—are but imperfectly known. Their hexatomicity, however, appears to be established by the analogy subsisting between certain of their compounds and the similar hexatomic compounds of the non-metals sulphur and selenium, thus:

With the atomic weights S 32, Se 79.5, Te 129, and W 184, the specific heats of the atoms of sulphur, selenium, tellurium, and tungsten approximate to the number 6.2; while the specific heat of the atom of molybdenum, Mo 96, has yet to be ascertained. The vapour-densities of the oxychloride and trioxide of sulphur are the halves of their respective atomic weights, and their molecules consequently accord with the normal two-volume standard. The corresponding compounds of molybdenum are also volatile, but at too high a temperature to allow of the ready determination of their vapour-densities; and the same remark applies to the hexachloride and oxychloride of tungsten. But trioxide of tungsten is fixed in the fire, while trioxide of tellurium decomposes into dioxide and free oxygen, as does indeed vaporised trioxide of sulphur at a red heat. The semi-metal tellurium is isomorphous with, and in its general characters and behaviour very closely resembles, the semi-metal antimony, the two elements obviously occupying analogous positions in the sulphur and phosphorus groups respectively. The exact position of molybdenum in relation to the sulphur-group proper is as yet undetermined. With an atomic weight much inferior, it exhibits metallic characters far more perfectly than tellurium, while its most characteristic compounds have just the constitution and general properties which those of a metallic analogue of the sulphur elements might be expected to present.

The association of tungsten with molybdenum, though scarcely established beyond question, is not improbably analogous to that of bismuth with antimony, tin with lead, &c., the difference in atomic weight between the several pairs of elements being almost identical. The trioxides of tellurium, molybdenum, and tungsten occur as insoluble powders, which have many properties in common, including a marked tendency to form anhydro-salts with the stronger bases, and a capability of acting as feeble bases to the stronger acids. Tungstic acid WH_2O_4 , and its hydrate $WH_2O_4.H_2O$, have been described by Riche (Ann. Ch. Phys. [3] 1. 5), but molybdic acid is not known in the isolated state, though its salts, formed on the type MoM_2O_4 , are very well defined. Graham, however, obtained both molybdic and tungstic acids in the colloid form, as perfectly soluble compounds possessed of considerable stability, having decidedly acid characters, and altogether closely resembling one another (Proc. Roy. Soc. xiii. 340). The trisulphides of molybdenum and tungsten are powerful sulphanehydrides, which combine with sulphide of potassium to form beautiful red and orange crystalline salts. The several elements now under consideration are not only hexatomic, but also tetraatomic, and in some cases even diatomic, just as we have seen that the pentad elements are triatomic and even monatomic. Thus we have:—

..	SCl^4	$SeCl^4$	$TeCl^4$	$MoCl^4$	WCl^4
..	SO^2	SeO^2	TeO^2	MoS^2	WS^2
OH^2	SH^2	SeH^2	TeH^2	$MoCl^2$..
OCl^2	SCl^2	..	$TeCl^2$	MoO .	..

Tungsten is also pentatomic, forming the compounds WCl^5 and WBr^5 (Roscoe): consequently, like vanadium it exhibits an exception to the general law of the variation of atomicity by pairs of units.

The vapour-densities of the hydrides of oxygen, sulphur, selenium, and tellurium, and of the chlorides of oxygen and sulphur among the dyad compounds, as well as of dioxide of sulphur among the tetrad compounds, are the halves of their atomic weights; or their respective molecules correspond with the normal two-volume standard. Of the other compounds above tabulated, the protoxide of molybdenum, and the disulphides of molybdenum and tungsten, are not volatilisable, while the remainder, though volatile, have not had their vapour-densities determined. In a classification of elements according, not to their maximum, but to their most characteristic atomicities, oxygen, sulphur, and by consequence selenium and tellurium, would probably be regarded as dyadic.

GROUP VII. Heptad Metals.—The elements referred to at the commencement of this article under the head of non-metallic monads, namely chlorine, bromine, and iodine, have the property of forming, in addition to their respective monohydrides, well-marked triad, pentad, and even heptad compounds, examples of which last are afforded by their respective quadrox-acids, $Cl^{VII}HO^4$, $Br^{VII}HO^4$, $I^{VII}HO^4$, and $(I^{VII})_2O^7$. Iodine, though in some sense the representative of tellurium and antimony, cannot rank even as a semi-metal, but we are acquainted with at least one perfect or malleable metal which in some of its compounds may be regarded as heptadic, namely manganese. With the atomic weight 55, the atom of manganese has the same specific heat as the atoms of chlorine, bromine, and iodine, namely 6.2, and forms a well-defined acid of moderate stability, the permanganic acid $Mn^{VII}HO^4$, whose potassium-salt, $Mn^{VII}KO^4$, is isomorphous with perchlorate of potassium, $Cl^{VII}KO^4$. The general properties of manganese, however, will be more appropriately considered in the

next section devoted to the iron family of metals. The succeeding table of chlorides, hydrides, and hydrates is not without interest as exhibiting the characteristic atomicities of the different groups of elements:—

Li ⁺ Cl ⁻	G ⁺⁺ Cl ⁻	B ⁺⁺⁺ Cl ⁻	C ⁺⁺⁺⁺ H ⁻	N ⁺⁺⁺⁺ H ⁻	O ⁺⁺ H ⁻	FH
Na ⁺ HO	Mg ⁺⁺ H ⁻ O ⁻	Al ⁺⁺⁺ H ⁻ O ⁻	Si ⁺⁺⁺⁺ H ⁻ O ⁻	P ⁺⁺⁺⁺ H ⁻ O ⁻	S ⁺⁺ H ⁻ O ⁻	Cl ⁺ HO ⁻

Having regard to the upper line of compounds, carbon may be regarded as placed at the apex of two converging series of elements of increasing atomicities; while having regard to the lower line of compounds, it will appear as the middle term of a single series. It is observable that the atomic weights of carbon and silicon correspond very closely with the arithmetical means of the atomic weights of the elements placed respectively on the same lines with them, for $\frac{12}{2} = 6$ and $\frac{28}{2} = 14$.

GROUP VIII. Iron Metals.—The elements previously discussed are for the most part capable of being arranged in two general divisions, accordingly as they combine with an odd or even number of atoms of halogen or hydrogen. To such of them as combine with two, four, or six atoms of chlorine, &c., the designation artriad, and to those which combine with one, three, five, or seven atoms of chlorine, &c., the designation perissad may be conveniently applied. Vanadium and tungsten, however, as already observed, unite both with odd and with even numbers of halogen elements; and the same property is exhibited by the metals now to be considered. Such elements may not inappropriately receive the designation of peris-artiad. Among the members of this group attention will be more especially directed at first to the metals iron, nickel, copper, manganese, and cobalt. The most ordinary of the several series of compounds formed by these metals correspond closely with the similar compounds of zinc, in their saline constitution, water of hydration, crystalline form, and general chemical properties. Accordingly, if zinc is to be regarded as dyadic with the atomic weight 65, then iron, nickel, copper, manganese, and cobalt must also be regarded as dyadic, and receive the atomic weights given on the upper, instead of the formerly received atomic weights given on the lower of the following lines:—

Fe 56	Ni 59	Cu 63.5	Mn 55	Co 59
Fe 28	Ni 29.5	Cu 31.75	Mn 27.5	Co 29.5

With these doubled atomic weights, the iron-metals will have the normal specific heat expressed approximately by the number 6.2, instead of the abnormal specific heat expressed by the number 3.1; and several other advantages resulting from the duplication will be manifested further on. Adopting, then, the atomic weights which are in harmony with the specific heats of the metals, the ordinary ferrous, manganous, &c., salts will be represented as dyad compounds by the formulæ $M^{++}Cl_2$, $M^{++}O$, $SM^{++}O$, &c. Some evidence also of the existence of tetrad compounds is afforded by pyrolusite, $Mn^{++}O_2$, iron-pyrites, $Fe^{++}S_2$, and an artificial sulphide of nickel, $Ni^{++}S_2$. Moreover, according to experiments made by the author, there would appear to exist an unstable tetrachloride of manganese, $MnCl_4$, corresponding to the unstable tetrachloride of lead, $PbCl_4$, just as the peroxides of the two metals, MnO_2 and PbO_2 , also correspond with one another. Be this as it may, the ferrates and manganates, $Fe^{++}K_2O_4$ and $Mn^{++}K_2O_4$, analogous to the sulphates SK_2O_4 , furnish decisive examples of the existence of hexad compounds; and the mutual analogy of these three classes of salts affords an obvious argument in favour of adopting the atomic weights Mn 55 and Fe 56, whereby alone they can all three be represented by analogous formulæ. The association with one another of the five metals now under consideration centres in the remarkable parallelism subsisting between nickel and cobalt. By its intermediate properties nickel serves to connect iron and copper with one another; while its relationship to the former metal corresponds evidently with that of cobalt to manganese. The association of copper with iron through the intervention of nickel seems scarcely to receive that thorough recognition to which, in the author's opinion, it is entitled (Phil. Mag. xiii. 486), apparently because of the facility with which they may be analytically separated from one another. The three metals have the same atomic volume, namely 88, which is likewise that of manganese, cobalt, and possibly chromium, but of no other metal whatever. Their specific gravities, calculated or experimental, occur in regular sequence, as do also their atomic weights. Iron is the most infusible and weldable, then nickel, then copper. The three metals are soluble in hydrochloric acid with evolution of hydrogen, iron most readily, then nickel, then copper; they precipitate the somewhat basylous metals, tin and cadmium, from their boiling solutions; and alike form salts of a marked green colour, complementary in some measure to the pink colour of manganous and cobalt salts. Their hydrates are soluble in sal-ammoniac and ammonia, iron to a slight extent only, then nickel, copper most of all. Their sulphides are soluble in hydrochloric acid with evolution of sulphuretted

hydrogen; but while the precipitation of sulphide of iron may be prevented by a slight acidulation, that of nickel requires a larger proportion, and that of copper a very much larger proportion of acid. The sulphates of iron and nickel crystallise with seven atoms of water, and are isomorphous with one another; but sulphate of copper usually crystallises with five atoms of water, and is isomorphous with the corresponding sulphate of manganese. On the other hand, the sulphates of iron and copper crystallise together in all proportions, the mixed salt being heptahydrated and having the form of sulphate of iron, or pentahydrated and having the form of sulphate of copper, according to the preponderance of either metal. Again, the double potassium-sulphates of all three metals crystallise with six atoms of water, and are isomorphous. It is evident, however, in comparing the five metals with one another, that manganese and iron, which are at one extremity of the series, have a tendency to form hyper-oxides, and that copper, which is at the other extremity, has a tendency to form hypo-oxides, while cobalt and nickel are intermediate both in position and tendencies. Now, it is just some of these distinctive peroxidised compounds of manganese and iron on the one hand, and suboxidised compounds of copper on the other, that furnish us with illustrations of perissal forms of combination. Thus, manganese, whose general artind character is shown by its forming dyad, tetrad, and hexad compounds, as we have already seen, is nevertheless indisputably perissal in the permanganates. The permanganates, $Mn^{VI}KO_4$, for example, resemble the corresponding perchlorates $Cl^{VII}KO_4$, in constitution, stability, solubility, crystalline form, specific heat, &c., and, with the high atomic weight for manganese, are expressible by similar formulæ. The perchloric and permanganic acids are analogous, unstable, and powerfully oxidising compounds. Dumas has also described a volatile perchloride of manganese, supposed to be a heptachloride $Mn^{VII}Cl_7$, which is decomposed by water into hydrochloric acid and permanganic acids; but H. Rose has shown that it is an oxychloride $Mn^{VII}OCl_7$, analogous to chromic oxychloride $Cr^{VI}OCl_3$.

Passing to the opposite member of the iron group, we find copper furnishing a whole series of salts, which, represented by the most simple formulæ with the doubled atom of copper, Cu_2 , agree closely in chemical constitution and properties, as well as in specific heat and crystalline form, with the corresponding salts of the monad metal silver. Cuprous chloride $CuCl$, and silver chloride $AgCl$, agree in the following characters. They have the same specific heat and crystalline form; are producible as white precipitates insoluble in water, but soluble in ammonia and in boiling hydrochloric acid, to form colourless solutions. They dissolve also in solutions of the alkaline chlorides forming similar double salts, which Becquerel obtained electrolytically in crystalline forms belonging to the regular system. The bromides and iodides of the two metals correspond with one another and with the chlorides, in form, solubility, reaction with ammonia, production of double salts, &c. &c. The amorphous oxides, Cu_2O and Ag_2O , resemble one another, but oxide of copper has alone been obtained in crystals, which are octahedral. The sulphides exhibit a remarkable correlation. Cuprous sulphide, Cu_2S , is dimorphous, and while the artificial compound is isomorphous with silver-glance, Ag_2S , in the regular system, the native form or copper-glance is isomorphous with silver-copper-glance, $AgCuS$, in the trimetric system. Miargyrite and antimonial copper are similarly constituted compounds, $AgSbS_2$ and $CuSbS_2$ respectively, while bournonite $Pb^{II}CuSbS_4$, and red silver $Ag^{II}SbS_4$, are similar and isomorphous. The convertibility of cuprous into cupric compounds constitutes, indeed, the only marked peculiarity of behaviour distinguishing them from the similar compounds of silver. So long as they continue to be cuprous compounds, the resemblance between them and their silver analogues is as great as that between the corresponding compounds of any two associated metals. But despite the analogy of cuprous to silver chloride, for instance, and of permanganic to perchloric acid, it has been proposed to double the molecular formulæ of all cuprous and permanganic compounds, and consequently to express them by formulæ dissimilar to those of their respective silver and chlorine analogues. By this means the formulæ $Cu^{II}Cl_2$ and $Mn^{VII}H_2O_4$, for instance, will certainly be brought into harmony with the law of even numbers, but at a very heavy sacrifice of simplicity and analogy. Fully admitting the great and not generally appreciated value of Laurent and Gerhardt's law, it must yet be remembered that these distinguished chemists themselves pointed out its inapplicability to the perissal compounds of the iron metals, save by admitting for each metal two different atoms represented by two different symbols; and it may also be asked whether the received mode of expressing Laurent and Gerhardt's law might not be advantageously modified into some such dictum as the following, that "in every compound the sum of the atomicities or equivalencies is an even number."

Just as copper and manganese, though usually dyadic, are associated with monadic silver and heptadic chlorine respectively, so is iron, though usually dyadic, associated with triadic aluminium. Ferric chloride, oxide, and compounds generally, present such

an analogy to aluminic chloride, oxide, and compounds generally, that similar formulæ ought necessarily to be applied to the similar series of bodies. Confining ourselves for simplicity's sake to the case of the two chlorides, we have to choose between the formulæ $AlCl^3$ and $FeCl^3$, on the one hand, and the formulæ Al^3Cl^6 and Fe^3Cl^6 , on the other. The more complex expression for ferric chloride, Fe^3Cl^6 , is certainly recommended by several considerations of indisputable importance, but not, in the author's opinion, of such paramount importance as positively to require its adoption. Thus, the formula Fe^3Cl^6 is in harmony with the law of even numbers, as usually enunciated; but the simpler formula would agree equally well with the law, if modified in its expression as above proposed. Again, the formula Fe^3Cl^6 is in harmony with the constitution of certain mixed and basic salts of ferricum investigated more particularly by Scheurer-Kestner (Bull. Soc. Chim. 1863, p. 344), in which one-sixth of the acid radicle combined with the ferricum differs from the remaining five-sixths, as in ferric aceto-nitrate, for example, $Fe^2(C^2H^3O^2)^3(NO^3)^2HO$, or $Fe(C^4H^3O^2)^3Fe(NO^3)^2HO$; but the number of salts known to be formed on duplicate types is now so great as to deprive this consideration of any extreme consequence. No one, for instance, contends that the constitution of tri-acid oxalate of potassium, $C^2H^3O^4.C^2HKO^4$, necessitates the accordance of the formula $C^2H^3O^4$ to oxalic acid. Lastly, the formula Fe^3Cl^6 is in harmony with the vapour-density of ferric chloride, as determined by Deville, who found that two volumes of vaporised ferric chloride contain twice 56 parts of iron, and six times 35.5 parts of chlorine, just as two volumes of vaporised chloride of aluminium contain twice 27.5 parts of aluminium, and six times 35.5 parts of chlorine. This is no doubt a very important result, and one which, unless susceptible of some explanation direct or analogical, would be decisive of the question. But there are undoubtedly certain bodies of which the ascertained vapour-densities, no matter how accounted for, are, as a matter of experiment, discordant with the chemical analogies of the respective bodies. For instance, the quantity of phosphorus which bears to the molecule of phosphoretted hydrogen, PH^3 , the same relation that the molecule of nitrogen bears to the molecule of ammonia, has only half the bulk of these several molecules. Again, the quantity of white arsenic which bears to the molecule of arsenious chloride, $AsCl^3$, the same relation that the molecule of water bears to the molecule of hydrochloric acid, has only half the bulk of these several molecules. Lastly, the quantity of aluminic chloride which bears to the molecule of aluminic ethide, $AlEt^3$, the relation which the molecule of corrosive sublimate bears to the molecule of mercuric ethide, has only half the bulk of these several molecules. In these cases, the results flowing from the anomalous volumes of free phosphorus, arsenious oxide, and aluminic chloride are corrected by having regard to the normal volumes of other volatile compounds of phosphorus, arsenic, and aluminium respectively; and bearing in mind the great resemblance between aluminic and ferric compounds, is it not probable that the ascertained volume of ferric chloride may be also anomalous, and hereafter be proved to be anomalous by comparison with the vapour-densities of as yet undiscovered volatile compounds of ferricum having normal volumes? Whether it be that certain bodies have two distinct condensations corresponding to two distinct molecules, of which in some cases the ordinary, in some cases the extraordinary, and in other cases both, are experimentally known; or whether it be that these bodies have each in reality but a single condensation and a single molecule, which in some cases has not been correctly ascertained, through the employment of a temperature insufficient to render the body perfectly elastic, the fact remains that the ascertained vapour-densities of a considerable number of bodies are not in harmony with their most characteristic chemical relations, though, in the majority of instances, these anomalous results are divested of importance by other determinations of vapour-density, either of the same bodies raised to higher temperatures, or of allied bodies having a more decided volatility. Even allowing, therefore, that ferric chloride, at the temperature at which its density was taken, has the molecular formula Fe^3Cl^6 , it by no means follows that under other conditions it may not have the simpler molecular formula $FeCl^3$. Accepting the formula $FeCl^3$ for the chloride, certain other important ferric compounds will be represented as follows: the hydrates as $Fe^3H^3O^3$ and $Fe^3H^3O^2$; the oxide as Fe^3O^3 ; the black oxide as $FeOFe^3O^3$ or Fe^3O^4 ; and iron alum as $KFe^3(SO^4)^2.12H^2O$. Thus the constitution of iron alum, like that of common alum, becomes a direct consequence of the triatomicity of its characteristic metal. Cobalt and manganese both form oxides corresponding to ferric oxide, and manganese forms in addition an unstable manganic chloride, Mn^3Cl^3 , and manganic alum, $KMn^3(SO^4)^2.12H^2O$. These formulæ of course depend for their warranty upon those for the corresponding ferric compounds.

Chromium, according to the normal atomic heat 6.2, will have the atomic weight 52.5, instead of 26.25, the heretofore generally received number. It forms three well-defined chlorides, viz. the dichloride Cr^2Cl^2 , trichloride Cr^3Cl^3 , and oxychloride or chlorochromic acid $Cr^4Cl^2O^2$. This last compound is readily volatile, and its ascer-

tained vapour-density being the half of its atomic weight, its molecule is referrible to the normal two-volume standard. The dichloride and trichloride are also volatilisable compounds, but their vapour-densities have not been determined. That of the trichloride, however, would probably present the same peculiarity as the analogous aluminic and ferric trichlorides; and judging solely by vapour-density, the compound would consequently have to be represented by the formula $\text{Cr}^{\text{III}}\text{Cl}^3$. Chromous salts correspond closely to ferrous salts in their general behaviour, and especially in their absorption of nitric oxide, with production of dark brown compounds. They have, however, a red or bluish colour more like that of cobalt salts. Alkaline sulphhydrates throw down a black precipitate of chromous sulphide, and caustic alkalis a pale coloured precipitate of chromous hydrate, soluble in sal-ammoniac and ammonia. The tendency of this last precipitate to become peroxidised greatly exceeds even that of ferrous hydrate, as proved by its gradual deoxidation of water with liberation of hydrogen. The double sulphate of chrome and potassium, $\text{K}^2\text{Cr}^{\text{VI}}(\text{SO}_4)^2 \cdot 6\text{H}_2\text{O}$, is isomorphous with the similar salts of iron, &c. Chromic and ferric compounds again present a general similarity of behaviour, though with some well-marked differences. Chrome-iron $\text{Fe}^{\text{III}}(\text{Cr}^{\text{VI}})^2\text{O}^4$ is isomorphous with magnetic oxide $\text{Fe}^{\text{III}}(\text{Fe}^{\text{III}})^2\text{O}^4$; chromic oxide $(\text{Cr}^{\text{VI}})^2\text{O}^3$, with hematite $(\text{Fe}^{\text{III}})^2\text{O}^3$; chromic alum $\text{KCr}^{\text{VI}}(\text{SO}_4)^2 \cdot 12\text{H}_2\text{O}$, with iron alum $\text{KFe}^{\text{III}}(\text{SO}_4)^2 \cdot 12\text{H}_2\text{O}$, &c. But, unlike the similar compounds of ferricium, chromic oxide is decomposed by fusion with carbonated alkalis into chromate and an inferior oxide; chromic hydrate is soluble in cold solutions of caustic alkalis; while chromic salts react with sulphide of ammonium to produce chromic hydrate and sulphuretted hydrogen, though this last difference may possibly be only one of degree depending upon the difficult reducibility of chromic compounds: for it is doubtful at least whether the precipitate produced by sulphide of ammonium in ferric salts is other than a mixture of sulphur and ferrous sulphide. Chromic anhydride $\text{Cr}^{\text{VI}}\text{O}^3$, the most characteristic of all the compounds of chrome, forms well defined salts having the same general formula as the manganates, ferrates and sulphates $\text{XM}^{\text{VI}}\text{O}^4$. Its resemblance to vanadic anhydride, a compound belonging to the pentad group, has been already noticed (p. 968).

Uranium is usually classed with the iron metals, for although possessing but little resemblance even to them, it has still less to any other group of elements. The formulae of uranium-compounds, and the atomic weight of uranium must be regarded for the present as not finally determinable, since the analytical results cannot yet be controlled by any considerations derived from vapour-density, isomorphism, specific heat, or strict chemical analogy. The proportion of uranium which unites with 35.6 parts of chlorine in uranous chloride, is found to be 60 parts, and accordingly the atomic weight of the metal may be fixed at 60, or 120, 180, 240, &c. The ready volatility of uranous chloride is in favour of its molecule containing more than one, and indeed even more than two atoms of chlorine; while the high specific gravity of uranium, 18.4, would seem to associate its atomic weight with those of such heavy metals as tungsten, specific gravity 17.6, atomic weight 184; gold, specific gravity 19.3, atomic weight, 196.6; and platinum, specific gravity 21.5, atomic weight 197; although the correlation of specific gravity with atomic weight is undoubtedly subject to many vagaries. Altogether, it seems most advisable to assume that the atomic weight of uranium is 240, and that the formula of its subchloride is U^2Cl^4 , while that of uranous chloride is UCl^4 , and that of uranic oxychloride $\text{U}^{\text{VI}}\text{O}^2\text{Cl}^2$. Aqueous uranous chloride and uranous salts in general have a marked green colour, but furnish a red-brown gelatinous hydrate, soluble in carbonated alkalis. They are completely decomposed by the earthy carbonates, with evolution of carbonic anhydride. They yield a black precipitate with sulphide of ammonium, and oxidise readily by exposure to air. Uranic salts are of a lemon-yellow colour, and possess in a characteristic degree the property faintly shadowed forth in a few trials of antimony, chromium, &c., of being derived from their respective acids by a substitution, not of metal, but of metallic oxide for basic hydrogen, which metallic oxide is transferable from one compound to another, throughout the entire series of double decompositions for which the salts are liable. There is accordingly no hexachloride UCl^6 or hexnitrate $\text{U}(\text{NO}_3)^6$, but only an oxychloride UOCl^2 and oxynitrate $\text{UO}^2(\text{NO}_3)^2$. The oxychloride is a yellow, crystalline, readily fusible, but difficultly volatilisable mass. The nitrate crystallises in lemon-yellow prisms decomposable by heat, and yielding in succession a uranic hydrate, uranic oxide, uranous-uranic oxide. Both salts are soluble in water, forming lemon-yellow fluorescent solutions. These are converted into uranous solutions by sulphuretted hydrogen, with separation of sulphur, and are otherwise very easily reducible. They give a dark brown precipitate with excess of alkaline carbonate, the form soluble crystallisable double compounds with excess of alkaline carbonate, the potassium-salt having the formula $2\text{K}^2\text{O}^2 \cdot (\text{U}^{\text{VI}}\text{O}^2)^2\text{CO}^3$; and yield precipitates of alkaline uranate, $\text{K}^2\text{O} \cdot 2\text{UO}^3$, for instance, with caustic alkalis.

GROUP IX. Platinum Metals.—The metals palladium, rhodium, ruthenium, platinum, iridium, and osmium, though differing considerably in many of their chemical habits, are nevertheless separated from all other elements, and associated with one another, by certain very distinctive characters. With the normal atomic heat 6.2, their several atomic weights will be as follows:—Os 199, Ir 197, Pt 197, Pd 106.5, Ru 104, and Rh 104. The specific gravities of the first three metals having the higher atomic weights are about 21, while those of the other three having the lower atomic weights are between 11½ and 12. Each of the metals of low atomic weight seems to be more especially correlated with some particular one of the metals of high atomic weight, palladium with platinum, rhodium with iridium, and ruthenium with osmium; and all six metals are found associated together naturally in the metallic state. They are all infusible save at the highest temperatures, such as that attainable with the oxyhydrogen blowpipe. The platinum metals resemble certain metals of the iron family in the polychromatism of their salts, the permanency of their double cyanides, and the perisartind seriation of their chlorides, oxides, &c.

Palladium and platinum belong to the class of noble metals. They do not combine directly with oxygen, even at the highest temperatures, while their chlorides and indirectly produced oxides are reducible to the reguline state by heat alone. Their di- and tetrachlorides are the most characteristic of their combinations. Palladium is said to form an inferior chloride PdCl , and oxide Pd_2O , analogous to those of cuprous, but its ordinary salts are typified, as above remarked, by the dichloride PdCl_2 , and the tetrachloride PdCl_4 . The former is crystallisable and soluble in water, while the latter is known only in solution. They both produce crystallisable double salts with chloride of potassium, ammonium, &c. Platinum forms a well-defined crystalline tetrachloride PtCl_4 , which by a regulated heat is convertible into the dichloride PtCl_2 , insoluble in water but soluble in hydrochloric acid, and also in solution of the tetrachloride, forming apparently a double or intermediate chloride Pt^2Cl_6 or PtCl_3 . Both the di- and tetrachlorides of platinum form crystallisable double salts with the chlorides of alkali-metal, &c.

Rhodium and iridium, though permanent in the air at all temperatures when in the massive state, seem to be more readily oxidisable by treatment with chemical agents than the metals last considered. At the same time their several oxides are reducible by heat alone. The trichlorides are the most characteristic of their respective chlorides, and are typical of their ordinary salts. Rhodium forms an insoluble dichloride RhCl_2 of which very little is known, and a soluble deliquescent rose-coloured trichloride RhCl_3 , one molecule of which combines with either two or three molecules of alkaline chloride to form beautiful crystalline salts of a rose-red colour, whence the name of the metal. Iridium, so called from the polychromatism of its salts, forms a dichloride IrCl_2 , insoluble in water, but forming soluble red-coloured salts with the alkaline chlorides; a comparatively stable trichloride IrCl_3 , whose solution is of an olive-green colour, and whose double potassio-chloride has the formula $3\text{KCl}.\text{IrCl}_3$; and a tetrachloride IrCl_4 , known only in the form of its potassio-chloride $2\text{KCl}.\text{IrCl}_4$, which is a crystallisable salt of almost black colour, while the corresponding hydrated oxide $\text{IrO}_2.2\text{H}_2\text{O}$, occurs as an indigo-blue precipitate.

Ruthenium and osmium differ from the other platinum-metals in the degree of their oxidisability, ruthenium forming a trioxide RuO_3 and a tetroxide RuO_4 corresponding to the unknown chlorides RuCl_3 and RuCl_4 , and osmium forming both a trioxide OsO_3 , with its corresponding chloride OsCl_3 , and a stable volatile tetroxide OsO_4 ; these tetroxides are the most highly oxidised compounds of any elements whatsoever. Ruthenium and osmium, moreover, are directly oxidisable, and even combustible, in air, at temperatures varying with their state of aggregation, and the resulting oxides are not reducible by any increased temperature to which they have been subjected. Ruthenium forms three chlorides RuCl_2 , RuCl_3 , and RuCl_4 , with the corresponding oxides RuO , Ru_2O_3 , and RuO_2 , of which the trichloride and trioxide are typical of ordinary ruthenium salts. The dioxide, produced by heating ruthenium with osmium in a current of air, though not volatile *per se* is carried over by the osmic vapours and condenses as a crystalline sublimate of well-defined square prisms. Fused with nitre, all the above oxides of ruthenium produce a soluble orange-yellow salt, the ruthenate of potassium $\text{K}_2\text{O}.\text{RuO}_2$. Osmium forms four chlorides OsCl_2 , OsCl_3 , OsCl_4 , and OsCl_5 , all of which volatilise by heat and produce double salts with the alkaline chlorides. It also forms the corresponding oxides OsO , Os_2O_3 , OsO_3 , OsO_4 and an additional oxide OsO^4 . The trioxide, though scarcely known, save in the form of its potassio-salt $\text{K}_2\text{O}.\text{OsO}_3.2\text{H}_2\text{O}$, which crystallises in rose-coloured octahedra, seems to have decided acid characters. Tetroxide of osmium OsO_4 is a very remarkable body. It occurs in flexible acicular colourless crystals, freely soluble in water. It fuses at a gentle heat and boils at 100° , with conversion into a pungent noxious

our, whose specific gravity is the half of its atomic weight. It seems to be quite void of acid properties, since it is evolved from its solution in caustic alkalis by simple ebullition, while its solution in water has no action upon litmus paper.

The numerical relations subsisting between the atomic weights of the several elements have for a long time past excited considerable interest among chemists, and we are not unnaturally led to a considerable amount of speculation.

Not unnaturally, results of a considerable amount of experimental investigation show that these atomic weights range from 1 (hydrogen) to 240 (uranium) the question arises whether the varied chemical properties of the elements are distributed among them haphazard, or according to some definite system, of which the relationship subsisting between their several atomic weights may possibly serve as a key. Now the atomic weights, as distinguished from the combining proportions, of yttrium, cerium, lanthanum and didymium, must be regarded for the present as quite unknown. Out of the 58 elements, however, whose atomic weights have been more or less well determined, 46 have atomic weights ranging from 1 to 137 in an almost broken succession; 10 of the other 12 have atomic weights ranging from 184, that of tantalum, to 210, that of bismuth; while the remaining two, namely thorium and uranium, have the closely approximating atomic weights 238 and 240 respectively.

In this table the symbols of the elements are arranged in the order of the atomic weights, except only in the case of tellurium, the symbol of which is placed immediately above instead of below that of iodine; its atomic weight has perhaps been somewhat over-estimated. Departing from the order of numerical seriation in this particular only, it is remarkable with what facility the symbols of the elements may be arranged in parallel lines and columns, corresponding with a natural classification of the elements themselves into analogous groups and series. Indeed a study of the tire number of elements at present known would seem to indicate that they are one and all associated with each other by a certain community of relationship, of which the well-known gradation and parallelism in properties and atomic weights, of the members of the alkali and earth-alkali, and of the halogen and oxygen families of elements, afford only the most prominent examples.

Taking the second line of the table as an illustration, it is observable that the first ten metals symbolised therein are distinguished from all the others by the property of forming one chloride only and that a dichloride; further that the metals in the even-numbered columns of this line, namely magnesium 24, zinc 65 and cadmium 112, are permanent in the air, volatilisable in the direct, and basylous in the inverse order of their atomic weights, and are otherwise specially associated with one another, while the similarly associated metals in the first three alternate or even-numbered columns, namely calcium 40, strontium 87.5 and barium 137, are quickly oxidisable in the air, are practically non-volatile, and are basylous in the direct instead of in the inverse order of their atomic weights; and similarly on the other lines of the table, the elements are divisible into sub-groups according to their odd and even positions.

Such being the relationship of the elements placed in the same line, the relationship those placed in the same column is of a different kind. Taking the third and seventh columns by way of illustration, it is observable that the consecutive elements each column have closely consecutive atomic numbers; that the element on the first line forms a monochloride, that on the second line a dichloride, that on the third

* See also Mendelejeff, *Ann. Ch. Pharm.* viii. Supplementband, 123.

* See also Mendelejeff, Ann. Ch. Pharm. viii. Supplementband, 122.
The notes of interrogation indicate that the position in the series of the elements to which they are attached is doubtful.

a trichloride, and that on the fourth a tetrachloride; while those on the fifth, sixth and seventh lines form oxides or oxychlorides corresponding to a penta, hex- and heptachloride respectively.

The preceding table shows also that about five-and-twenty new elements are required to fill up the gaps in the different series; and it is possible that other new elements may be discovered with atomic weights greater than that of uranium.

Another idea suggested by comparisons like the foregoing is that it scarcely seems probable that bodies capable of being arranged in so well-marked a numerical series are really elementary and mutually independent; a more likely supposition seems to be that the gradation of properties and atomic numbers manifested by these bodies depends on their possession of different increments of common material. W. O.

METALUMINA. This name is applied by Graham (Chem. Soc. J. xv. 24) to the soluble dihydrate of aluminium (i. 159) which Crum obtained by the action of heat on a solution of the acetate. Graham has shown that it may be prepared by dialysing a solution of the acetate altered by heat, nearly all the acetic acid passing through, and a solution of metalumina remaining on the dialyser (p. 717). The solution is tasteless, and neutral to test-paper.

METALYSIS. Döbereiner's name for CATALYSIS.

METAMARGARIC ACID. An acid isomeric with margaric acid, $C^{17}H^{34}O_2$, said by Frémy (Ann. Ch. Phys. [2] lxx. 121) to be obtained, together with metaleic acid, by treating with cold water the mixture of sulphomargaric and sulpholeic acids produced by the action of strong sulphuric acid upon olive-oil. On pressing the resulting precipitate, and treating it with alcohol of 36 per cent., the metamargaric acid is dissolved out. It is white, crystalline, insoluble in water, easily soluble in alcohol and ether, melts at 50° , and exhibits the composition of margaric acid. Most of its salts were also found by Frémy to exhibit the composition of the margarates, but the silver salt yielded 27—85 per cent. silver, which is nearly the composition of stearate of silver. Altogether, it is doubtful whether the acid obtained as above was a definite compound.

METAMERISM. See ISOMERISM (p. 415).

METAMECONIC ACID. Syn. with COMENIC ACID (i. 1103).

METAMORPHINE. An opium-base, the hydrochlorate of which is obtained, as a residue, in the preparation of opium-tincture by means of lime and sal-ammoniac. The hydrochlorate is soluble in 25 pts. of cold, and 2 pts. of hot water, reacts neutral, and gives no precipitate, either with ammonia or with the fixed alkalis or their carbonates. When dried at 100° , it contains 12.2 per cent. HCl (hydrochlorate of morphine, $C^{17}H^{19}NO^3.HCl.3H^2O$, contains 9.7 per cent.).

The free base separated from the sulphate by digestion with carbonate of barium, and exhaustion with alcohol, crystallises in stellate groups of prisms. It is not bitter; dissolves in 600 pts. cold, and 70 pts. boiling water, in 330 pts. of alcohol of 90 per cent. at ordinary temperatures, and in 9 pts. at the boiling heat; it is nearly insoluble in ether. It dissolves easily in caustic potash, less easily in ammonia and alkaline carbonates. With nitric acid of specific gravity 1.33 it forms a yellow solution. The aqueous solution is gradually coloured yellow by iodic acid; not altered by ferric chloride. Chloride of gold first forms with it a yellowish colour, then a flocculent brownish precipitate, but produces no blue coloration. (G. C. Wittstein, Arch. Pharm. [2] cv. 141.)

METAMORPHISM. A term applied to the transformation of minerals and rocks by physical and chemical action. (See GEOLOGY, CHEMISTRY OF, ii. 831.)

METAMYLENE. A compound polymeric with amylene, probably $C^{20}H^{48}$, contained in the higher portion of the distillate produced by heating amylic alcohol with sulphuric acid. It has not been obtained pure. (Balard.)

METANAPHTHALENE. See NAPHTHALENE.

METANTIMONIC ACID. See ANTIMONY (i. 324).

META-OCTYLENE. See OCTYLENE.

META-OLEIC ACID. An oily acid produced by the action of water on sulpholeic acid. It is insoluble in water, easily soluble in ether, very slightly in alcohol. (Frémy, Ann. Ch. Phys. [2] xv. 128.)

METAPLECTIC ACID. See PLECTIC ACID.

METAPLECTIN. See PLECTIN.

METAPHOSPHORIC ACID. See PHOSPHORUS, OXYGEN-ACIDS OF.

METASILICATES. Silicates of the augite type, $M'SiO_3$ or $M'O.SiO_3$ (Odling.)

METASTANNIC ACID. See STANNIC ACID, under TIN.

METASTYROL. Syn. with METACINNAMENE (see CINNAMENE, i. 982).

METATARTARIC ACID. See TARTARIC ACID.

METATEREBENTHENE. See TURPENTINE.

METATUNGSTIC ACID. See TUNGSTIC ACID.

METAXITE. Breithaupt's name for a fibrous variety of serpentine from Schwarzenberg in Saxony. Hardness = 2 to 2.5. Specific gravity = 2.52. Greenish-white, with weak pearly lustre. Contains, according to Kühn (Ann. Ch. Pharm. lix. 369), 43.48 per cent. silica, 41.00 magnesia, 2.20 ferrous oxide, and 12.95 water (= 99.63).

METAXOÏTE. A mineral resembling metaxite, occurring in green serpentine at Lupikko, near Pitkäranta in Finland. Hardness, between calcspar and gypsum. Specific gravity = 2.58 to 2.61. Colour, from greenish-black to white. Sometimes apparently amorphous, sometimes radio-fibrous and spherical. Contains, according to an analysis by C. G. Hällsten (Jahresb. 1862, p. 749), 40.63 per cent. silica, 10.17 alumina, 6.78 ferric oxide, 12.88 magnesia, 16.03 lime, and 12.88 water (= 99.37).

METEORITES. *Aerolites. Uranolites.* This name includes, not only those mineral bodies which are known to have fallen on the earth's surface from the celestial spaces, but likewise a great number of others, which, though their origin is not actually known, yet agree so closely with known meteorites in mineralogical and chemical constitution, as to justify the conclusion that they are also of meteoric origin.

The numerous analyses which have been made of meteorites, both the older ones by Howard, Klaproth, and Vauquelin, and those of more recent date by Berzelius and others, have demonstrated in them the presence of about 18 elementary bodies, all of which likewise occur in terrestrial minerals, viz. aluminium, calcium, carbon, chromium, cobalt, copper, iron, magnesium, manganese, nickel, oxygen, phosphorus, potassium, silicon, sulphur, titanium, tin, and perhaps also in some cases, antimony, arsenic, chlorine, hydrogen and lead.

Meteorites are divided into two classes, distinguished as Meteoric Iron, and Meteoric Stones. Meteoric iron consists chiefly of metallic iron alloyed with nickel, contains no oxidised compound, and has in general the characters of ordinary bar-iron. Meteoric stones are mixtures of several minerals, chiefly silicates (felspar, augite, olivin), which also play an important part in terrestrial minerals.

This division is however merely artificial, inasmuch as many meteorites are mixtures of meteoric iron with masses of meteoric stone, or with one or more of the minerals occurring in meteoric stones. If the metallic portion predominates, the meteorite is classed as meteoric iron, as for example the so-called Pallas meteorite, found at Krasnojarsk in Siberia, or that of Atacama, both of which contain larger or smaller masses of olivin imbedded in cavities in the iron. If, on the other hand, the earthy portion (the silicates) predominates in amount, the meteorite is called a meteoric stone, although the fine splinters or grains of meteoric iron diffused through the mass may give it an appearance quite different from that of meteoric stones consisting wholly of earthy minerals. Meteoric stones containing metallic iron are much more numerous than those consisting wholly of earthy minerals.

1. Meteoric Iron.

A mass of meteoric iron is always a mixture, the constituents being sometimes visible, sometimes revealing themselves only to chemical investigation. The chief part of the mass consists of iron alloyed with nickel, and perhaps always with a small quantity of cobalt. This admixture of nickel is usually regarded as a proof of the meteoric origin of numerous masses of metallic iron found on or a little below the surface of the earth, whose actual fall has not been observed. The amount of iron in meteoric iron usually varies from about 80 to 95 per cent.; the nickel from 6 to 10 per cent.

In many cases, sulphide of iron is visibly disseminated through the mass, sometimes in the form of rather large cylindrical grains. This sulphide is often regarded as magnetic pyrites, FeS_2 (p. 401), which does indeed occur in some meteorites; but

those examined by Rammelsberg (Pogg. Ann. cxxi. 363) contained protosulphide of iron, FeS . Part of this sulphide is however distributed through the mass of the iron in so minute a state of division, that it can be detected only by the evolution of sulphydric acid, which takes place on dissolving the iron in acids.

Moreover all specimens of meteoric iron, when dissolved in hydrochloric acid, leave a residue, varying in amount from a fraction to several units per cent. This residue is also a mixture, and appears under the microscope to consist chiefly of a distinctly crystallised compound, which chemical analysis shows to contain iron, nickel, and phosphorus, usually mixed with carbon and silica. The carbon, a very remarkable constituent of meteoric iron, appears to occur therein, as in pig-iron, in two different states, viz. partly as graphite, partly in chemical combination with the iron. On this account, the entire quantity of the carbon is never found in the residue, the solution of meteoric iron in acids being attended with the emission of the same offensive odour that is evolved in the solution of pig-iron. The silica is derived from silicide of iron. It is evident from these considerations that chemical analysis can never afford a perfectly exact picture of the individual compounds present in meteoric iron.

Many specimens of meteoric iron, when polished and afterwards etched with an acid, exhibit on their surface peculiar crystalline configurations, called 'Widmanstätt's figures.' These figures were attributed by Berzelius to an alloy of iron and nickel disseminated through the mass, which alloy, being less soluble in acids than the pure iron, was brought to light when the latter was removed from the surface by the acid. But certain samples of meteoric iron, viz. that of the Cape (p. 379), and those found at Greenville in Tennessee and at Clairborne in Alabama, all very rich in nickel (containing from 9 to 12 per cent. of that metal), do not exhibit these figures: hence their formation is much more probably due to the phosphide of nickel and iron, or *Schreibersite* (Shepard's *Dyslytite*), which, as already observed, forms the principal part of the residue left on dissolving the iron in acids.

The analysis of the principal mass of the iron often exhibits small quantities of phosphorus, doubtless arising from partial decomposition of the phosphide by the acid used to dissolve the iron.

The following are analyses of a few specimens of meteoric iron, taken from Rammelsberg's *Mineralchemie* (pp. 902-920).

1. Found at Elbogen in Bohemia, and known as 'der verwünschte Berggraf.' Specific gravity, as determined by different observers, 7.74—7.83. In the solution of this meteorite in hydrochloric acid, Berzelius found traces of tin and copper. The residue is a mass having a carbonaceous aspect, and consisting partly of metallic spangles.

2. Bohumilitz in Bohemia. Specific gravity = 7.14 (Steinmann); 7.61—7.71 (Rumler). Dissolves in hydrochloric acid, with evolution of fetid hydrogen gas; the solution contains traces of phosphorus.

3. Seeläsgen near Schwiebus. Specific gravity = 7.59 (Partsch); 7.63—7.1, (Duflos); 7.7345 (Rammelsberg). In the metallic mass are enclosed cylindrical grains of a sulphide of iron, of brownish-yellow colour, specific gravity 4.787, quite insoluble in hydrochloric acid, and containing, according to Rammelsberg's analysis, 75.37 per cent. ferrous sulphide, 0.71 sulphide of copper, 2.73 chrome-iron, and 19.83 nickel-iron (= 98.64).

4. Krasnojarsk in Siberia. Discovered in 1772 by Pallas, and hence called the Pallas mass. The best known meteorite of the class, consisting of metallic nickel-iron mixed with olivine and a little sulphide of iron. Specific gravity = 7.78—7.84 (Rumler). The residue insoluble in hydrochloric acid contains, besides charcoal, a heavy substance having the metallic lustre and appearing distinctly crystalline under the microscope.

5. Cosby's Creek, Cooke County, Tennessee. Specific gravity = 7.26 (Rumler); 7.267 (Bergemann). The residue, according to Bergemann, is a black powder amounting to 2.075 per cent., containing yellow shining magnetic laminæ and a black coaly mass.

6. Braunau in Bohemia. Fell on July 14, 1847. Specific gravity = 7.714 (Beinert). The insoluble residue is a mixture of an amorphous coaly powder, with greyish-white, metallic-shining, strongly magnetic laminæ. In the mass is imbedded a magnetic sulphide of iron, which dissolves in hydrochloric acid without separation of sulphur, but leaves very small quantities of charcoal and chrome-iron.

7. Coshuila in Mexico. A mass weighing 252 pounds. Specific gravity = 7.81. The phosphide is said to amount to 1.55 per cent.

8. Atacama in Chile. Specific gravity = 7.89. The cavities contain a brownish-white silicate of calcium and iron, containing phosphoric acid (perhaps olivine).

9. Niakornak in Greenland. Specific gravity = 7.073. When dissolved it gives off hydrogen gas containing sulphur and carbon, and leaves at first a crystalline

powder, which afterwards disappears, leaving nothing but carbon. This crystalline powder is not the ordinary phosphide of nickel and iron, but a carbide of iron containing from 7.23 to 11.06 per cent. carbon. The residue insoluble in hydrochloric acid also contains traces of earths reacting like yttria and zirconia.

10. Cape of Good Hope, near the Sunday and Bushman river. Specific gravity = 6.63—7.94 (Rumler); 7.66 (Wehrle). The residue consists, according to Urlicoechea, of brownish-yellow and colourless granules; according to Böcking, of phosphide of nickel and iron. This meteorite is one of those which do not exhibit any Widmanstätten figures when etched with acids (p. 378).

* With magnesium.

† With calcium and arsenic.

11, 12, 13. From the Valley of Toluca, near Xiquipilco, in Mexico, where numerous masses of meteoric are found, of various sizes, and often converted into ferric hydrate, even to the middle of their substance. According to Krauz, many of the lumps contain, in cavities on their surfaces, magnetic oxide of iron, both massive and crystallised, and apparently not resulting from recent oxidation; also graphite, sulphide of iron, and laminae of nickel-iron-phosphide.

Analysis 11 is of a lump weighing 13 lbs., which gave off sulphydric acid when dissolved; 12 of a mass weighing 220 lbs., much oxidised; 13 of a less oxidised mass weighing 5½ lbs.

14. Zacatecas in Mexico, with sulphide of iron disseminated through it. Specific gravity = 7.48 (Bergemann); 7.35 (Rumler). Dissolves in hydrochloric acid, with evolution of fetid hydrogen gas.

15. Also from Zacatecas. Soft, tough, difficult to break, with distinctly laminated structure on the surface. The residue, insoluble in dilute hydrochloric acid, consists of a small quantity of a black flocculent substance resembling graphite, but dissolving in strong hydrochloric acid with evolution of sulphydric acid, — and of nickel-iron-phosphide containing 75.02 Fe, 14.52 Ni, and 10.23 P. Müller (Chem. Soc. Qu. J. xi. 236) regards this meteorite as distinct from that from the same locality analysed by Bergemann (14), inasmuch as the latter contains neither carbon nor chrome-iron.

2. Meteoric Stones.

This name, as already observed, is applied to meteorites consisting wholly, or for the most part, of earthy minerals (silicates). The older analyses of these stones by Howard, Klaproth and others, determined merely the entire chemical constitution without regard to the possible existence of different minerals in the same stone; but the later researches of Berzelius, Gustav Rose, Rammelsberg, &c., have shown that meteoric stones are mixtures of certain silicates, viz. olivin, augite, labradorite, &c., with or without meteoric iron. In some few cases, the mineralogical constituents of a meteorite can be distinguished by physical examination; thus Gustav Rose showed that the meteorite of Juvenas contains magnetic pyrites, augite, and a felspar resembling labradorite, and determined the form and other properties of these minerals. But generally speaking, the individual constituents of the meteorite are not recognisable by the sight, even on microscopical examination, and can only be determined by chemical analysis. If the stone contains only two minerals, one of which is decomposable by acids, while the other is not, the determination of their nature is comparatively easy and certain; but if both are attacked by acids with equal facility, or not attacked at all, or if the stone is a mixture of three or more minerals, chemical analysis can only show what minerals *probably* exist in it.

The following are examples of meteoric stones whose constitution has been most accurately determined:

a. Containing Meteoric Iron.

1. Chantonnay, Depart. Vendée. Fell on August 5, 1812. Ground-mass partly black, partly grey, with black streaks. Specific gravity = 3.46—3.48 (Rumler). The silicates of this meteorite consist of 51.12 per cent. olivin, 38.01 augite, and 10.01 labradorite (= 99.16), (Rammelsberg.)

2. Seres in Macedonia. Fell in June 1818. Dark grey mass, of specific gravity 3.71 (Rumler). Consists of a mixture of silicates, in which are imbedded a mineral resembling olivin, nickel-iron, and magnetic pyrites. (Berzelius.)

3. Blansko in Moravia. Nov. 25, 1833. Dark grey; specific gravity = 3.70 (Rumler). From an analysis by Berzelius, Rammelsberg calculates the composition at 21.3 per cent. nickel-iron, 2.97 sulphide of iron, 0.63 chrome-iron, 35.18 olivin, 33.88 augite, and 17.30 labradorite.

4. Chateau-Renard, Depart. Loiret, in France. June 12, 1841. Grey; specific gravity = 3.66 (Dufrénoy); 3.54 (Rammelsberg). Consists, according to Dufrénoy, of 50 per cent. olivin, and about 10 per cent. nickel-iron, the remainder appearing to be made up chiefly of augite and labradorite.

5. Utrecht (Louvenhoutje near). June 2, 1843. Ground-mass nearly white, fusible. Specific gravity, 3.57—3.65 (Baumhauer). Consists, according to Baumhauer, of a mixture of olivin, augite, oligoclase, nickel-iron (10 per cent.), and magnetic pyrites.

6. Klein-Wenden, near Nordhausen in the Harz. Sept. 16, 1843. Grey ground-mass, intermixed with yellowish-green and black grains. Specific gravity = 3.7006 (Rammelsberg). Consists, according to Rammelsberg, of olivin, augite, and labradorite, in which are imbedded nickel-iron (about 20 per cent.), and a small quantity of pyrites (magnetic pyrites or protosulphide).

7. Montréjeau (Clarac, Aussen), Depart de la Haute-Garonne. December 9,

1858. Greyish-white ground-mass, interspersed with numerous brownish round granules of various sizes, and greyish-white magnetic metallic granules and laminae. Specific gravity = 3.30. (Filhol and Lemoysie); 3.50 (Chance and Moitessier). Contains, according to the latter, 10.04 per cent. matter attracted by the magnet (= 8.36 Fe, 1.56 Ni, 0.07 metallic phosphides, 0.05 adhering ferrous sulphide), 1.71 chrome-iron, 5.72 ferrous sulphide, 45.08 olivin, and 37.51 feldspar and hornblende (Jahresb. 1859, p. 850.)

B. Without Meteoric Iron.

1. Stannern in Moravia. May, 22, 1808. Specific gravity = 3.19 (Vauquelin); 3.01—3.17 (Rumler). Consists, according to Rammelsberg, of 65.15 per cent. augite, 34.92 anorthite, 0.98 magnetic oxide of iron, and 0.54 chrome-iron (= 101.59). The augite contains 1 at. magnesium to 2 at. calcium and 3 at. iron.

2. Juvenas, Dept. Ardèche, France. June 3, 1821. Specific gravity = 3.11 (Rumler). Consists, according to Rammelsberg, of 62.65 per cent. augite, 34.66 anorthite, 0.60 apatite, 0.25 titanite, 1.35 chrome-iron, 1.17 magnetic oxide of iron, and 0.25 magnetic pyrites (= 100.83).

3. Jonzac, near Barbezieux, Dept. de la Basse-Charente, France. June 13, 1819. Specific gravity = 3.08 (Rumler). Resembles the preceding in properties and composition.

4. Lontalax, near Wiborg, in Finland. December 13, 1813. Specific gravity = 3.07 (Rumler). Contains, according to Berzelius, magnetic iron ore, and silicates, of which 93.55 per cent. consist of a silicate decomposable by nitro-muriatic acid, and having the composition of olivin (containing 1 at. iron to 2 at. magnesium), with traces of copper, tin, and alkali-metals, and 6.45 of a silicate of aluminium, iron, manganese, and calcium, the composition of which has not been determined; also a small quantity of chrome-iron.

5. Bishopville, South Carolina. March 1813. A very peculiar stone, consisting for the most part of a white mineral partly crystallised and apparently monoclinic. Specific gravity = 3.116 (Shepard); 3.039 (Waltershausen). Melts before the blowpipe to a white enamel. Contains also small quantities of magnetic pyrites and ferric oxide imbedded in the mass. An analysis of the white mineral by Waltershausen gave 67.14 per cent. silica, 1.48 alumina, 1.70 ferric oxide, 27.11 magnesia, 1.82 lime, and 0.67 water, whence it appears to consist essentially of chladrinite, $2\text{Mg}^2\text{O} \cdot 3\text{SiO}_2$.

A mineral, perhaps identical with this, obtained from a mass of iron said to be from the neighbourhood of Grimma, was described 30 years ago by Stromeyer.

6. Concord, New Hampshire. White porous mass, which melts on the edges before the blowpipe, colouring the flame yellow. Contains, according to B. Silliman, 84.97 per cent. silica, 12.07 and 2.22 soda, an unusual composition which may be represented by the formula $\text{Na}^2\text{O} \cdot 4\text{SiO}_2 + 9\text{Mg}^2\text{O} \cdot 4\text{SiO}_2$; considered doubtful by Rammelsberg.

7. Bokkeveld, Cape Colony. October 13, 1838. Soft black mass with a few lighter points. Emits a bituminous odour when heated, and contains a resinous or waxy substance soluble in alcohol, which easily melts and chars. When ignited in contact with the air, even after being freed from the resinous substance, it burns and gives off a quantity of carbonic anhydride equivalent to 1.6 per cent. carbon. It therefore contains carbon, to which in fact its black colour is due. It contains water, even after drying at 100°. It also yields when heated a small quantity of sublimate containing sulphate of ammonium. It acts but slightly on the magnetic needle, and therefore contains but little magnetic iron. It contains 3.8 per cent. sulphur, but does not give off any sulphur when heated, or evolve sulphydric acid gas when treated with hydrochloric acid: hence it cannot contain either iron pyrites, magnetic pyrites, or ferrous sulphide. Wöhler considers the sulphur as belonging to a sulphide of nickel and iron, $\text{Ni}^{18}\text{Fe}^2\text{S}^2$, which requires 1.3 nickel to 2.6 iron, quantities agreeing with those found by analysis. From an analysis by Harris, made under Wöhler's direction, Rammelsberg concludes that the stone contains 6.94 per cent. nickel-iron-sulphide, 1.11 chrome-iron stone, 84.32 olivin, 5.46 undecomposable silicates, and 1.92 carbon and bituminous matters.

8. Kaba, near Debreczin, in Hungary. April 15, 1857. Dark grey, earthy ground-mass, containing white and greenish grains, resembling olivin, also numerous black spherules, very brittle, hollow within, and consisting of a colourless crystalline mineral and a black mineral. The ground-mass exhibits nothing metallic, but yields a small quantity of iron to the magnet. Its composition, according to Wöhler's analysis, is similar to that of the preceding, with addition of 3.55 per cent. magnetic pyrites. When ignited in oxygen gas, it gives off carbonic anhydride, together with a little water and a crystalline sublimate. Alcohol extracts from it a white carboniferous substance resembling paraffin and scheererite, very fusible, partly volatile, partly decomposed by

heat, with separation of carbon. When the pulverised stone, freed from this substance by alcohol, is ignited in oxygen, it turns brown and gives off water, even after it has been well dried.

9. Alais, Dept. du Gard, France. May 15, 1806. Black friable mass, which breaks up in water to a greyish-green pulp, having a strong argillaceous odour, and becomes covered with saline efflorescences when exposed to the air. Water dissolves out 11·6 per cent. of the stone, consisting chiefly of alkaline and earthy sulphates resulting from oxidation of sulphide of iron contained in the stone. The powder, after exhaustion with water, yields by distillation 0·96 per cent. grey sublimate, 4·33 carbonic anhydride, 6·58 water, and 88·15 fixed residue, consisting of effloresced olivin and partially oxidised magnetic iron ore, together with a silicate undecomposable by acids, and containing magnesia and ferrous oxide, with small quantities of alumina, nickel, tin, and copper.

From all that is at present known respecting the constitution of meteorites, Rammelsberg draws the following conclusions:—

Meteoritic iron consists of an alloy of iron and nickel (the latter generally amounting to 6—9 per cent., or 1 at. nickel to 10—15 at. iron) mixed with nickel-iron-phosphide or *Schreibersite*, sulphide of iron, carbon, carbide of iron, and chrome-iron, sometimes also with olivin and magnetic oxide of iron.

Meteoritic stones. (a.) Most of them contain more or less meteoric iron, imbedded in a ground-mass, probably consisting of olivin, augite, and labradorite. Stones of this class are rich in iron and magnesium, poor in calcium and aluminium.

(b.) A smaller number, containing no meteoric iron, may be subdivided into—

α. Containing *olivine*. These consist of olivin probably with augite and labradorite, and contain magnetic oxide of iron, sulphide of iron (meteorites of Lontalax, Bokkeveld, Kaba, Alais).

β. Not containing *olivine*. They consist of augite and anorthite, together with small quantities of sulphide of iron, magnetic oxide of iron, and chrome-iron (meteorites of Stannern, Juvenas, Jonzac). They are rich in calcium and aluminium.

γ. The meteorite of Bishopville consists mainly of a silicate called *chladnite*, having the composition $2\text{MgO} \cdot 3\text{SiO}_2$.

Shepard (Sill. Am. J. [2] ii. 377; vi. 402; xv. 363) mentions also a number of other minerals, some of them quite new, as existing in meteorites; but their existence is by no means satisfactorily established.

Meteorites are covered over their entire surface, except where recently fractured, with a thin black, more or less shining crust, which, on closer examination, presents a fused slag-like appearance. It is doubtless produced by the strong but transient heating which the meteorite undergoes during its rapid transit through the earth's atmosphere. This rise of temperature, which is further indicated by the luminosity of those meteorites whose fall has been observed, and by the fact that some of them, on reaching the earth, have been found in a heated and even incandescent state, may be attributed, in part at least, to the friction of the stone against the particles of the air which it meets in its rapid passage.

Liquid or gelatinous masses called meteoric mud (*Meteorschleim*) have sometimes been observed to fall; but their chemical constitution has not been examined: they are said indeed to consist of volatile substances which cannot easily be preserved, and altogether the accounts respecting them are very vague and unsatisfactory. A mass of this kind which fell near Gotha in the year 1815, is described as of gelatinous consistence and of dark grey colour by moonlight. It smelt like liver of sulphur, and when held in the observer's hand, melted to a thick liquid which quickly evaporated, diffusing a strong odour like that of burning sulphur and phosphorus. (Handw. d. Chem. v. 224.)

The so-called meteoric dust (*Meteorstaub*), which has sometimes been observed to fall from the air on ships at a considerable distance from land, is in all probability of terrestrial origin. Gibbs (Pogg. Ann. lxxi. 367) found in a specimen of such dust which fell on a ship in the Atlantic Ocean (after deduction of 18·53 per cent. water and organic matter), 45·58 per cent. silica, 20·55 alumina, 9·39 ferric oxide, 4·22 manganic oxide, 11·77 calcic carbonate, 2·21 magnesia, 3·645 potash, 2·33 soda, and 0·31 cupric oxide. Ehrenberg has detected infusoria in some specimens of supposed meteoric dust, and supposes that it is transported from one part of the earth to another by violent storms. It may sometimes also be of volcanic origin (i. 420).

For further details respecting the chemical constitution of meteorites, see Rammelsberg's *Mineralchemie* (pp. 901–952).

On the physical and chemical constitution, classification, &c. of meteorites, see the following works:

Gustav Rose.—*Beschreibung und Eintheilung der Meteoriten auf Grund der Sammlung im mineralogischen Museum zu Berlin* (aus den Abhandlungen der königl. Academie der Wissenschaften zu Berlin, 1863), Berlin, 1864.

A chronological list of meteorites from the earliest records down to A.D. 1824, is given in the *Annales de Chimie*, tome xxx., and in Ure's *Dictionary of Chemistry*, 3rd. ed., pp. 619-624.

METHAL. Syn. with MYRISTIC ALCOHOL.

METHIDE, ALUMINIC. $AlCl^3$, or $AlMe^3$. (Buckton and Odling, Proc. Royal Soc. xiv. 19.) When mercuric methide and excess of aluminium clippings contained in sealed tubes are heated for some hours in a water-bath, the mercury completely replaces the aluminium, thus:

By rectification out of contact with air, the aluminic methide is obtained as a colourless mobile liquid, which at a little above 0° congeals into a transparent crystalline mass. It boils steadily at 130° . At and above 220° its vapour-density was found to be 2.8, the theoretical density calculated for the formula $AlMe^3$ being 2.5. But its density corrected for expansion, increases rapidly with every decrease of temperature, so that at 160° — 163° it becomes 3.96 or 4.1; while at its boiling point 130° , it is as high as 4.4, which approximates to the theoretical density 5.0 calculated for the formula Al^3Me^3 . Aluminic methide takes fire spontaneously on exposure to air, burning with a very smoky flame and producing abundant flocculi of alumina discoloured by soot. By a regulated exposure to dry air, it absorbs oxygen, with production of a body apparently analogous to boric dioxymethide (p. 986). It is decomposed by water with explosive violence, and reacts with iodine to form iodo-derivatives and iodide of methyl.

Aluminic ethide, $AlEt^3$, is made by a precisely similar process, using mercuric ethide instead of mercuric methide. It is a colourless liquid which does not solidify at -18° . It boils at 191° , and its vapour-density taken at 234° was found to be 4.5, the theoretical density calculated for the formula $AlEt^3$ being 3.9. The excess of the experimental over the calculated density was obviously due to some unavoidable oxidation of the substance examined. Aluminic ethide takes fire spontaneously on exposure to air, and in its other chemical properties closely resembles the methyl compound. Cahours (Ann. Chim. Phys. [3] lviii. 5) observed that aluminium was attacked by the iodides of methyl and ethyl at 100° — 130° , and that the crude ethylated product reacted violently with zinc-chloride to form a very inflammable liquid which was doubtless aluminic ethide.

It is worthy of note, that the vapour-volumes of aluminic ethide ($AlEt^3 = 2$ vols.), and of aluminic methide at 220° and upwards ($AlMe^3 = 2$ vols.) are discordant with the vapour-density of aluminic chloride as determined by Deville ($AlCl^3 = 1$ vol.); but that the vapour-volume of the methide taken at 130° corresponds very nearly therewith. Hence it would seem that the only observed volume of the chloride, like the volume of the methide at 130° , is anomalous, probably in consequence of its vapour not having been sufficiently heated to acquire that perfection of elasticity under which alone the bulk of a vapour is regulated by the physical laws of temperature and pressure affecting gases.

METHIONIC ACID. An acid obtained by decomposing neutral sulphate of ethyl with water (Liebig). It has been shown by Buckton and Hofmann (Ann. Ch. Pharm. c. 163) to be identical with disulphometholic acid, $CH_3^2SO^2$. (See SULPHUROUS ETHERS.)

METHOKACETIC ACID. Syn. with METHYL-GLYCOLLIC ACID. (See GLYCOLIC ETHERS, ii. 916.)

METHPLUMBETHYL. Syn. with Plumbotrimethyl. (See LEAD-RADICLES, ORGANIC, p. 563.)

METHSTANNETHYL. See TIN-RADICLES, ORGANIC.

METHULMINE, AND METHULMIC ACID. (E. Hardy, Bull. Soc. Vol. III.

Chim. de Paris, 1862, p. 29, Jahresb. 1862, p. 388.) These are brown uncrystallisable substances, resembling the ulmic compounds, produced by the action of sodium and methylic alcohol on chloroform. The immediate products of the reaction are chloromethulmic acid and its sodium-salt, together with marsh-gas, carbonic anhydride, free hydrogen, and chloride of sodium:

Chloromethulmic acid is black, semifluid, has a pungent odour, and is soluble in alcohol.

By boiling with *potash*, it is resolved into methulmic acid, $\text{C}^3\text{H}^3\text{O}^2$, and dioxy-methulmic acid, $\text{C}^3\text{H}^3\text{O}^4$:

Methulmic acid is dark yellow, soluble in ether, uncrystallisable. It is converted by *bromine* into black, semi-fluid dibromomethulmic acid, $\text{C}^3\text{H}^3\text{Br}^2\text{O}^2$, which when treated with *sulphuric acid* at 60° , is resolved into carbonic anhydride and dibromide of hypomethulmene, $\text{C}^3\text{H}^3\text{Br}^2$, a yellow-brown solid substance, soluble in ether.

Dioxymethulmic acid, $\text{C}^3\text{H}^3\text{O}^4$, is black, uncrystallisable, insoluble in ether, soluble in alcohol.

Chlorethulmic acid, $\text{C}^3\text{H}^3\text{ClO}^2$, and chloramylulmic acid, $\text{C}^3\text{H}^3\text{ClO}^2$, are produced in like manner by treating chloroform with sodium and ethylic or amylic alcohol, and from these may be obtained derivatives similar in properties and homologous in composition to the methyl-compounds above described.—Dibromomethulmic acid, $\text{C}^3\text{H}^3\text{Br}^2\text{O}^2$, heated to 60° with *sulphuric acid*, is resolved into carbonic anhydride and dibromide of methulmene, $\text{C}^3\text{H}^3\text{Br}^2$, a brown-yellow substance, nearly insoluble in alcohol, but soluble in ether. It is converted by fuming *nitric acid* into pale yellow nitrobromide of methulmene, $\text{C}^3\text{H}^3(\text{NO}^2)\text{Br}$, precipitable by water, and by boiling *potash-lye* into bromomethulmene, $\text{C}^3\text{H}^3\text{Br}$, a black substance insoluble in acids and in alcohol, soluble in ether.

Compounds similar to the preceding are said to be formed by treating chloroform with sodium in conjunction with aldehydes, acetones, &c., and even when the chloroform is replaced by certain other compounds, especially the chlorides of carbon. It must be observed, however, that the composition of the majority of the compounds above mentioned has not been established by analysis, and therefore their formulæ must be considered doubtful, especially as none of them have been obtained in the crystalline form.

METHYL. CH^3 ; often denoted by the shorter symbol, Me ; in the free state, $\text{C}^2\text{H}^4 = \text{Me}^2$. The first of the series of alcohol-radicles, C^2H^{4+n} , bearing the same relation to wood-spirit that ethyl (C^2H^5) bears to common alcohol.

Frankland and Kolbe, in 1848 (Chem. Soc. Qu. J. i. 60), by decomposing cyanide of ethyl with potassium, first obtained a gas having the composition CH^3 or C^2H^4 , which they regarded as methyl. Kolbe, in the following year (*ibid.* ii. 173), obtained methyl by the electrolysis of acetic acid; and Frankland (*ibid.* ii. 297) afterwards prepared it by the action of zinc on iodide of methyl. From certain differences which he observed in the action of chlorine on the gas obtained by the first method, and that obtained by the second and third methods, Frankland concluded that the two were not identical but only isomeric, and that the latter was the true methyl, while the former consisted of hydride of ethyl, $\text{C}^2\text{H}^3\text{H}$; but the recent experiments of Schorlemmer (*vid. inf.*) have shown that the products obtained by the action of chlorine on the gases prepared by these several methods are really the same; whence, as no other difference has yet been observed between the two, it may be inferred, as most probable, that methyl in the free state is not only isomeric, but identical, with hydride of ethyl. (See HYDRIDES, p. 182.)

Preparation.—1. *By the electrolysis of Acetic acid.*—When a concentrated solution of acetate of potassium is subjected to the action of the electric current, a number of gaseous products are evolved, viz. carbonic anhydride, hydrogen, an inflammable, inodorous gas, and a gas which smells like ether; the last is completely absorbed by sulphuric acid (if the smallest quantity of chloride of potassium be present in the solution, chloride of methyl is formed). The gaseous mixture thus evolved, after being freed from carbonic anhydride, contained in one experiment, in 100 volumes: 0.7 vol. oxygen, 63.8 hydrogen, 32.6 methyl, 2.1 oxide of methyl, 0.8 acetate of methyl; in another experiment, 66 vol. hydrogen were obtained to 28 methyl. If the solution of acetate of potassium be divided by a porous diaphragm, so that the gases evolved at the two poles may be collected separately, nothing but hydrogen is evolved at the negative pole, while at the positive pole there is evolved a gaseous mixture, which,

after being treated with potash and with sulphuric acid, leaves nothing but methyl mixed with a small quantity of oxide of methyl. The decomposition is expressed by the following equation :

2. By decomposing *iodide of methyl* with *zinc*, the mode of operating being exactly similar to that already described for the preparation of ethyl from ethylic iodide (ii. 524).

If methyl be really identical with hydride of ethyl, we must add to these methods those already given for the preparation of the latter (ii. 533). Schorlemmer prepares it by the action of strong sulphuric acid on mercuric ethide (p. 925).

Properties.—Methyl is a colourless and odourless gas which burns with a bluish feebly luminous flame. It is somewhat soluble in *alcohol*, less soluble in *water* (see GASES, ABSORPTION OF, ii. 797). It is perfectly indifferent to the greater number of reagents. When mixed, either in the moist or dry state, with an equal volume of *chlorine*, it yields hydrochloric acid and chloride of ethyl, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Cl}$, together with a small quantity of monochlorinated chloride of ethyl, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{Cl}^{\text{H}}$ (Schorlemmer, Proc. Roy. Soc. xiii. 225). These results were obtained with methyl prepared by the electrolysis of acetic acid; and exactly the same products are formed by the action of chlorine on pure hydride of ethyl prepared by the action of sulphuric acid on mercuric ethide (Schorlemmer, Chem. Soc. J. xvii. 962). If the chlorine is used in excess, a larger quantity of the monochlorinated chloride of ethyl is obtained.

METHYL, ANTIMONIDES OF. See ANTIMONY-RADICLES, ORGANIC (i. 344).

METHYL, ARSENIDES OF. See ARSENIC-RADICLES, ORGANIC (i. 400).

METHYL, BORIDE OF. *Boric Methylide. Bormethyl.* $\text{B}(\text{CH}^{\text{H}})^{\text{O}}$. (Frankland, Phil. Trans. 1862, p. 176; Chem. Soc. Qu. J. xv. 373).—A gaseous compound homologous with boride of ethyl (ii. 525), produced by the action of zinc-methyl on borate of ethyl:

Preparation.—About two ounces of boric ether were mixed in a small flask with rather more than their own bulk of an ethereal solution of zinc-methyl, of such strength as to be spontaneously inflammable in a high degree. The flask, loosely corked, was placed in ice-cold water, and allowed to stand for a couple of hours until the reaction was complete; it was then furnished with a bent tube passing through a cork, to conduct the gas into a second flask placed in a freezing mixture of ice and salt; from this flask the gas passed into a third containing about half an ounce of strong solution of ammonia. The air in the whole of the apparatus was now displaced by nitrogen, and the flask containing the boric ether and zinc-methyl removed from the ice-cold water. A slow evolution of gas immediately commenced, and was kept up at a convenient speed by plunging the generating flask into cold water, to which heat was very slowly applied. The gas, in passing through the freezing mixture, deposited nearly the whole of the ether and zinc-methyl vapour with which it was contaminated; and on reaching the solution of ammonia, the boron-compound was instantaneously absorbed, whilst other gases, if present, passed through the ammonia unacted upon, and escaped into the atmosphere. The solution of ammonia soon became covered with a stratum of a lighter liquid, which increased in quantity until the stream of gas ceased to pass through. The ammonia-flask was now disconnected from the rest of the apparatus, and reserved for the next operation. The residue in the generating flask solidified to a crystalline mass on cooling.

To disengage the gaseous boron-compound from its combination with ammonia, the ammonia-flask was fitted with a funnel-tube terminating beneath the surface of the liquid, and a gas-delivery tube, the latter leading to a Liebig's potash-apparatus charged with concentrated sulphuric acid; finally, the opposite extremity of the latter apparatus was connected with a mercurial gas-holder. To prevent dangerous explosions, on the elimination of the spontaneously inflammable gas from its ammonia-compound, the whole of the air-spaces of the apparatus were filled with nitrogen. Everything being thus prepared, dilute sulphuric acid was gradually poured into the ammonia-flask through the funnel-tube, the contents of the flask being frequently agitated. No gas was evolved until the excess of ammonia was saturated; then, however, it was given off abundantly, and the addition of a few drops of sulphuric acid, from time to time, through the funnel-tube, served to keep up a convenient current. The gas was allowed to pass freely through the depressed mercurial gas-holder until a sample of it proved, by its perfect solution in ammonia, that all nitrogen had been swept from the apparatus.

The exit-tube of the gas-holder was then closed, and the gaseous boric methide was collected.

Properties.—Boric methide is at ordinary temperatures a colourless and transparent gas, possessing a peculiar and intolerably pungent odour, irritating the mucous membrane, and provoking a copious flow of tears. Its specific gravity is by experiment, 1.9108; by calculation, 1.93137. It retains its gaseous condition when exposed to a cold of 16° ; but at 10° , and under a pressure of three atmospheres, it condenses to a colourless, transparent, and very mobile liquid. It is very sparingly soluble in water, but very soluble in alcohol and in ether. In contact with atmospheric air, it takes fire spontaneously, burning with a bright green flame, which is very fuliginous if the volume of the flame be considerable. If the gas issues into the air through a tube $\frac{1}{16}$ of an inch in diameter, the amount of smoke is surprisingly great, two or three cubic inches of gas, when consumed in this way, filling the atmosphere of a capacious room with large comet-like flocks of carbonaceous matter. This effect is probably due, in part at least, to the formation of a superficial coating of boric acid, which envelopes the particles of carbon and prevents their combustion. When suddenly mixed with atmospheric air or oxygen, boric methide explodes with great violence. In contact with air, both boric methide and the vapour of boric ethide exhibit two distinct kinds of spontaneous combustion. Thus, when these bodies issue very slowly from a glass tube into the air, they burn with a lambent blue flame invisible in daylight, and the temperature of which is so low that a finger may be held in it for some time without much inconvenience. Under these circumstances partial oxidation only takes place, and it is to the products thus formed that the peculiar pungent odour of boric ethide and boric methide is due. When, on the other hand, these bodies issue into the air more rapidly, the lambent blue and nearly cold flame changes to the green and hot flame above mentioned.

Boric methide is not acted upon by nitric oxide or by iodine. Solution of acid chromate of potassium scarcely affects it, but the addition of concentrated sulphuric acid at once determines the reduction of the chromic acid. When boric methide is allowed to bubble through water into chlorine, each bubble burns explosively with a bright flash of light and separation of carbon. It has no tendency to unite with acids. Concentrated sulphuric acid has no action upon it; when mixed with hydriodic acid gas, it suffers no change; but, on the other hand, it is freely absorbed by solutions of the fixed alkalis, and by ammonia. If a very rapid current of the gas, mixed with half its volume of marsh-gas, be passed through a stratum of strong solution of ammonia only half an inch deep, not a trace of boric methide escapes absorption.

Ammonia-Boric Methide. $\text{NH}^3\text{B}(\text{CH}^3)^3$.—When dry ammoniacal gas is mixed with an equal volume of dry boric methide, both gases instantly disappear, with evolution of a considerable amount of heat, and production of a white, volatile, crystalline compound. The latter is also formed when boric methide is passed into solution of ammonia.

It is deposited from its ethereal solution in magnificent arborescent crystals, which rapidly volatilise without residue when exposed to the air. They have a caustic and bitter taste, and a very peculiar odour, in which both the smell of ammonia and of boric methide can be recognised. Ammonia-boric methide fuses at 56° , and boils at about 110° . In a current of air, or better, of carbonic anhydride, it sublimates at a very gentle heat, and condenses in magnificent arborescent crystals.

Its vapour-density is found by experiment to be 1.26, indicating that the molecule in the state of vapour occupies four volumes $\left(\frac{17 + 11 + 3 \cdot 16}{4} \times 0.0693 = 1.26\right)$, a result probably due, as in other cases, to the decomposition of the vapour at high temperatures (i. 469; ii. 816).

It scarcely absorbs a perceptible amount of oxygen at ordinary temperatures, even after several days' exposure to the gas, but takes fire below 100° , when heated in contact with the air. Its vapour is also very inflammable; thus when ammonia-boric methide is placed under the receiver of an air-pump, and the air is being withdrawn, the explosion of the mixture of air and vapour in the cylinders of the pump is frequently determined by the rise of temperature consequent upon the depression of the pistons when the rarefaction has become considerable.

Boric methide is also absorbed by aniline with great avidity. Acids expel the gas from this compound unchanged.

Trihydride of phosphorus has no action upon boric methide. A mixture of equal volumes of the two gases is spontaneously inflammable, burning with a yellowish-white flame, in which the characteristic green tinge attending the combustion of boric methide is no longer perceptible.

Compounds of Boric Methide with fixed Alkalis.—Boric methide combines with potash, soda, lime, and baryta. The potassium-compound $\text{K}^{\circ}\text{O} \cdot 2\text{B}(\text{CH}^3)$, obtained

by saturating a solution of caustic potash with boric methide, dries up in *vacuo* to a gummy mass. It may also be prepared by decomposing ammonia-boric methide with alcoholic potash, and evaporating in *vacuo*.

The *sodic*, *barytic*, and *calcic* compounds are also prepared by passing boric methide into the caustic solutions of the respective alkalis; they are soluble in water, and have an alkaline reaction.

METHYL BROMIDE OF. CH^3Br . *Methyl-hydrobromic ether. Hydrobromate of Methylene.* (Pierre, J. Pharm. [3] xiii. 156; Jahrb. 1847-48, p. 672.—Bunsen, Ann. Ch. Pharm. xlv. 44.)—Prepared by mixing, at a temperature of 5° or 6° , 50 pts. of bromine, 200 of methylic alcohol, and 7 of phosphorus. The temperature then rises spontaneously, and the phosphorus melts. The mixture must be cooled, decanted and very cautiously distilled. As thus obtained, it is a colourless liquid, of penetrating and slightly alliaceous odour; boils at 13° under a pressure of 0.759 met. (Pierre). It acts violently on cacodyl, forming bromide of cacodyl, and bromide of tetramethyl-arsonium (Cahours, Jahrb. 1861, p. 554):

A gas having the composition of bromide of methyl, is evolved on gently heating basic perbromide of cacodyl. It has a density of 3.253 (Bunsen, *Gaometry*, p. 121), by calculation, 3.224; a faint ethereal odour, and condenses at -17° into a thin, transparent colourless liquid. It burns with a yellowish flame when mixed with air, and explodes violently with oxygen on the application of flame.

METHYL CHLORIDE OF. CH^3Cl . *Methyl-hydrochloric ether. Hydrochlorate of Methylene.* (Dumas and Peligot (1835), Ann. Ch. Phys. lxi. 193).—Prepared by heating a mixture of 2 pts. chloride of sodium, 1 pt. of wood-spirit, and 3 pts. of strong sulphuric acid. Chloride of methyl then passes over as a gas, which may be collected over water; it is, however, contaminated with wood-spirit, sulphurous anhydride, and hydride of methyl.

Chloride of methyl is a colourless gas, having an ethereal odour and saccharine taste. Specific gravity 1.736. It does not condense at -18° . Water dissolves 2.8 times its volume of this gas at 16° .

Chloride of methyl burns with a white flame, green at the edges, producing water, hydrochloric acid, and carbonic anhydride. Passed through a red-hot tube, it is resolved, with slight deposition of charcoal, into a mixture of methylene and hydrochloric acid: $\text{CH}^3\text{Cl} = \text{CH}^2 + \text{HCl}$ (Dumas and Peligot). According to Perrot (Ann. Ch. Pharm. ci. 375), it deposits charcoal, and yields hydrochloric acid, marsh-gas, ethylene, carbonic oxide, naphthalene, and a substance which unites with bromine into a crystallised compound, melting at 40° and boiling at 220° . When passed over heated *potash-lime*, it yields formate and chloride of potassium, together with hydrogen gas:

When passed over phosphide of calcium at 200° or 300° , it yields a number of phosphoretted products, some of which appear to be organic bases. (P. Thénard.)

A gas having the same composition and physical properties as the preceding was obtained by Bunsen, by the action of heat on basic perchloride of cacodyl. Kolbe and Varrentrapp (Ann. Ch. Pharm. lxxvi. 37) also obtained a gas of the same composition, by leaving a mixture of equal volumes of marsh-gas and chlorine exposed to diffused daylight. Gerhardt (*Traité*, i. 566) regarded the first only of these products as CH^3Cl , the two latter as $\text{CH}^3\text{Cl.H}$.

Bayer (Ann. Ch. Pharm. cxvii. 181) finds that the gas produced from basic perchloride of cacodyl, exhibits the same degree of absorbability in water as that produced by heating wood-spirit with salt and sulphuric acid, the coefficient of absorption for both these gases being 5.034 at 7° ; 4.172 at 14° ; 3.462 at 20° ; and 3.034 at 25° . Moreover, the gas obtained by either of these methods forms a crystalline hydrate when passed into water cooled below 6° . On the contrary, the gas produced by the action of chlorine on marsh-gas does not form a crystalline hydrate, and has a much smaller coefficient of absorption in water (0.08 at 14°). Hence Bayer concludes that the gas produced by the decomposition of basic perchloride of cacodyl is identical with chloride of methyl, but that the gas resulting from the action of chlorine on marsh-gas is a substitution product isomeric but not identical therewith. According to Berthelot, on the other hand, the last-mentioned gas is really chloride of methyl, and may be converted into methylic alcohol by the action of potash.

Chloride of methyl is not attacked by chlorine in diffused daylight, but when exposed to the direct rays of the sun, it yields successively the three compounds—

Monochlorinated Chloride of Methyl	•	•	•	CH^3Cl^2
Dichlorinated Chloride of Methyl, or Chloroform	•	•	•	CHCl^3
Trichlorinated Chloride of Methyl, or Tetrachloride of Carbon	•	•	•	CCl^4

Monochlorinated Chloride of Methyl, $\text{CH}_3\text{Cl} = \text{C}(\text{H}_2\text{Cl})\text{Cl}$, is a very volatile liquid of exciting odour, similar to that of Dutch liquid. It boils at 30.5° . Specific gravity = 1.344 at 18° . Vapour-density 3.012. Treated with alcoholic potash, it yields but a slight precipitate of chloride of potassium, and distils almost without alteration. (For the other chlorinated compounds, see CHLOROFORM, and CARBON, CHLORIDES OF) (i. 765 and 919).

METHYL, HYDRATE OF. $\text{CH}_3\text{O} = \begin{matrix} \text{CH} \\ | \\ \text{H} \end{matrix} \text{O}$. *Methylic Alcohol, Wood-spirit, Wood-naphtha, Pyroxylic spirit, Esprit de Bois, Holzgeist, Holzessiggeist.*—This compound was first observed by Taylor in 1812 (Tilloch's Phil. Mag. ix. 315) among the products of the dry distillation of wood, afterwards more particularly examined by Dumas and Peligot in 1835 (Ann. Ch. Phys. lviii. 5; lxi. 193). It constitutes about 1 per cent. of the watery products of the dry distillation of wood; and in combination with salicylic acid (as methyl salicylic acid), it forms the chief constituent of the essential oil of winter-green (*Gaultheria procumbens*). According to Berthelot (Ann. Ch. Pharm. cv. 241) it may be produced artificially from marsh-gas (that compound when treated with chlorine yielding chloride of methyl, which by boiling with caustic potash is converted into methylic alcohol); and as marsh-gas itself can be formed synthetically from inorganic materials (p. 855), it follows also that methylic alcohol can be obtained by synthesis.

Preparation. 1. *Of Commercial Wood-spirit.*—The crude watery liquid (pyroligneous acid) obtained by the distillation of wood is decanted from the tarry portion of the distillate and redistilled; the first tenth which passes over is rectified, once or oftener over slaked lime, whereupon a large quantity of ammonia is given off; sulphuric acid is then added, which unites with the remaining ammonia and precipitates a certain quantity of tar; and the liquid is redistilled, and finally rectified several times over quicklime.

The crude wood-spirit thus obtained has a strong aromatic odour and turns brown on keeping. It contains considerable quantities of acetate of methyl, acetone, and a liquid called lignone by Weidmann and Schweizer, xylite by Völckel, the nature of which has given rise to considerable discussion, but which has lately been shown by Dancer (Chem. Soc. J. xvii. 222) to consist essentially of dimethyl-acetate of ethylene.

2. *Of Pure Methylic alcohol.* To obtain nearly pure methylic alcohol from commercial wood-spirit, advantage may be taken of the property which it possesses of forming with chloride of calcium a compound which is not decomposed by merely heating it to 100° , but gives off the methylic alcohol when distilled with water. The crude wood-spirit is saturated with fused chloride of calcium, and heated over the water-bath as long as anything volatile is given off; it is thus freed from the acetone, dimethylate of ethylene, &c., which do not unite with the chloride of calcium. The residue is then distilled with water, and the aqueous methylic alcohol thus obtained is rectified over quicklime (Kane, Ann. Ch. Pharm. xix. 164). According to Gould (Chem. Soc. J. vii. 311) it is advisable first to distil the wood-spirit with an equal volume of strong potash or soda-lye, in order to decompose the methylic acetate contained in it, sometimes in very large quantity, then to dehydrate with carbonate of potassium, and finally saturate with chloride of calcium as above.

To obtain perfectly pure methylic alcohol, however, it is necessary first to prepare a methylic ether, and then separate the alcohol from it by distillation with an alkali: *a.* Oxalate of methyl is prepared by distilling 1 pt. wood-spirit, 1 pt. sulphuric acid, and 2 pts. oxalate of potassium; the crystals of this ether, after being purified by pressure, are decomposed by distillation with water, and the distilled methylic alcohol is dehydrated by rectification over quicklime (Wöhler, Ann. Ch. Pharm. lxxxi. 376). *B.* Benzoate of methyl, prepared by passing hydrochloric acid gas into a solution of benzoic acid in wood-spirit, distilling and precipitating the portion collected above 100° with water, is decomposed by several hours boiling with soda-lye, the liquid is then distilled, and the distillate rectified over quicklime.

Methylic alcohol may also be obtained very nearly pure by distilling oil of winter-green (methyl-salicylic acid) with potash or soda-lye, and rectifying the distillate over quicklime; it retains, however, a slight odour of the oil.

Properties.—Methylic alcohol is a colourless mobile liquid, having a purely spirituous odour, like that of common alcohol (the empyreumatic odour of crude wood-spirit arises from the impurities). Specific gravity = 0.8142 at 0° . It boils at 60° to 66.5° , according to the nature of the vessel, and bumps strongly during boiling. It burns with a pale flame, mixes with water, alcohol, and ether, dissolves oils both fixed and volatile, also the greater number of resins, and is therefore much used as a solvent in place of common alcohol. It is also used for burning in spirit-lamps.

The following table exhibits the strength of pure wood-spirit, according to its density, as determined by Ure (Phil. Mag. [3] xix. 51):

Per-centage of Anhydrous Methylic alcohol (sp. gr. 0·8136, at 15°) in Wood-spirit.

Sp. gr.	Per cent.	Sp. gr.	Per cent.	Sp. gr.	Per cent.	Sp. gr.	Per cent.
0·8136	100·00	0·8674	82·00	0·9008	69·44	0·9344	53·70
0·8216	98·11	0·8712	80·64	0·9032	68·60	0·9386	51·54
0·8256	96·11	0·8742	79·36	0·9060	67·57	0·9414	50·00
0·8320	94·34	0·8784	78·13	0·9070	66·66	0·9448	47·62
0·8384	92·22	0·8822	77·00	0·9116	65·00	0·9484	46·00
0·8418	90·90	0·8842	75·76	0·9154	63·30	0·9518	43·46
0·8470	88·30	0·8876	74·63	0·9184	61·73	0·9540	41·66
0·8514	87·72	0·8918	73·53	0·9218	60·24	0·9564	40·00
0·8564	86·20	0·8930	72·46	0·9242	58·82	0·9584	38·46
0·8596	84·75	0·8950	71·43	0·9266	57·73	0·9600	37·11
0·8642	83·33	0·8984	70·42	0·9296	56·18	0·9620	35·71

Methylic alcohol unites directly with some substances, forming compounds like the alcoholates (i. 80), in which it takes the place of water of crystallisation. A solution of anhydrous *baryta* in wood-spirit leaves on evaporation crystals containing $\text{BaO} \cdot 2\text{CH}^3\text{O}$. *Chloride of calcium* is dissolved by wood-spirit with great rise of temperature, and the solution on cooling deposits large crystals of the compound $\text{CaCl}^2 \cdot 4\text{CH}^3\text{O}$, which may be heated to 100° without decomposition, but is decomposed by water, even at temperatures below 100°, yielding a distillate of methylic alcohol.

Decompositions.—1. Vapour of methylic alcohol passed through a red-hot tube yields acetylene, together with other products (Berthelot, *Compt. rend.* l. 805).—2. Pure methylic-alcohol burns in the air with a flame like that of common alcohol, without smoke.—3. In contact with *platinum-black* it is oxidised to formic acid.—4. *Potash* and *soda* dissolve in it readily, forming solutions which turn brown in contact with the air.—5. Methylic alcohol mixed with *sal-ammoniac* and heated in a sealed tube to 300°, yields the hydrochlorates of methylamine, dimethylamine, and trimethylamine (Berthelot).—6. *Hypochlorite of calcium* (bleaching powder) converts it into chloroform (CHCl^3).—7. A solution of potash in methylic alcohol treated with *bromine* or *iodine*, yields bromoform or iodoform.—8. With *potassium* it gives off hydrogen and is converted into methylete of potassium, CH^3KO ; similarly with *sodium*.—9. Heated with *alkaline hydrates*, it gives off hydrogen and yields a formate of the alkali-metal:

At higher temperatures and with excess of alkali, as when wood-spirit is passed over red hot potash-lime, the formate is converted into oxalate, and ultimately into carbonate, each change being attended with evolution of hydrogen (ii. 688).

9. Strong *sulphuric acid* acts upon methylic, partly in the same manner as upon ethylic-alcohol, producing methyl-sulphuric acid, $\text{CH}^3\text{H} \cdot \text{S}^2\text{O}^4$, which, when heated in contact with excess of wood-spirit, yields oxide of methyl. The action which takes place at higher temperatures differs, however, from that which takes place under similar circumstances between oil of vitriol and ethylic-alcohol in this respect, that no methylene (CH^2) appears to be produced, but neutral sulphate of methyl, $(\text{CH}^3)^2\text{SO}^4$, passes over.

10. *Chlorine-gas* passed into anhydrous wood-spirit acts upon it with considerable energy, each bubble of gas sometimes producing flame and detonation, and forms hydrochloric acid, together with several chlorinated products. [The chloracetones sometimes obtained in this reaction result in all probability from acetone contained in the wood-spirit]. According to Cloez (*Compt. rend.* xlviii. 642; *Jahresb.* 1859, p. 434) the final product of the action is a crystalline substance, parachloralide, $\text{C}^2\text{HCl}^3\text{O}$:

Bromine acts in a similar manner, producing parabromalide, $\text{C}^2\text{HBr}^3\text{O}$. Riche (*Ann. Ch. Pharm.* cxii. 323), by subjecting a mixture of wood-spirit and hydrochloric acid to the action of the electric current, obtained a chlorinated liquid containing $\text{C}^2\text{H}^2\text{ClO}$.

11. When methylic alcohol is added by drops to brown *chloride of sulphur*, SCI^2 , a violent action takes place, hydrochloric acid, sulphurous anhydride, and vapour of methylic chloride are evolved, a small quantity of chloride of thionyl, SOCl^2 , passes over, and the residue, after being heated to 80°, consists of chloride of sulphur, S^2Cl^2 , and the brown chloride of sulphur, SCI^2 , appears indeed to act like a mixture of S^2Cl^2 and

SCI^4 , the former remaining unacted upon, while the latter produces the following decomposition :

Chloride of thionyl also acts violently on methylic alcohol, producing hydrochloric acid and neutral sulphide of methyl, together with chloride of methyl and methylsulphurous acid :

Protochloride of sulphur (or chloride of sulphothionyl, SSCl^2) likewise acts strongly on methylic alcohol, hydrochloric acid and methylic chloride being evolved, while a small quantity of methyl-mercaptan passes over, and the residue contains methylsulphurous acid and neutral sulphate, besides separated sulphur. The first reaction is probably

and the chloride of thionyl then acts on the methyl-mercaptan, and probably also on further quantities of methylic alcohol, as shown by the following equation :

and by the last equation but two. (Carius, Ann. Ch. Pharm. cx. 209, cxi. 93.)

Ethylsulphurous chloride, $\text{C}^2\text{H}^5\text{ClSO}^2$ (the product of the action of pentachloride of phosphorus on ethyl-sulphites), acts on methylic alcohol (or more definitely on methylate of sodium), producing hydrochloric acid (or chloride of sodium) and methylsulphurous acid :

METHYL, HYDRIDE OF. Syn. with MARSH-GAS (p. 854).

METHYL, IODIDE OF. CH^3I .—Obtained by distilling 1 pt. of phosphorus, 8 pts. of iodine, and 12 or 15 pts. of wood-spirit, or according to Hofmann (Chem. Soc. J. xiii. 69), 1000 grms. iodine, 500 methylic alcohol, and 60 phosphorus. The distillate is mixed with water which separates the iodide of methyl, and the product is rectified in the water-bath over chloride of calcium and oxide of lead. It is a colourless liquid, slightly combustible, so that it does not burn well excepting in the flame of a lamp; it then diffuses abundance of violet vapours. Specific gravity = 2.237 at 22° ; 2.1992 at 0° (Pierre). Boils at 42.2° under a pressure of 0.752 met. (Andrews); at 43.8° under 0.750 met. pressure (Pierre). Vapour-density = 4.883. It is not attacked by hydrochloric acid gas.

Chlorine converts it into chloride of methyl, with deposition of iodine. Heated with metallic zinc in a sealed tube, it yields iodomethylide of zinc :

Heated with arsenide, antimonide, &c. of potassium or sodium, it yields the arsenides antimonides, &c., of methyl. Heated in a sealed tube with aqueous ammonia, it forms the iodides of ammonium, methyl-ammonium, di-, tri-, and tetra-methyl-ammonium, the first and last of these iodides being produced in greatest quantity. With magnesium it yields magnesian methide (p. 756), the action beginning even at ordinary temperatures; with aluminium, aluminic methide (p. 983).

METHYL, OXIDE OF. *Methylic ether.* $\text{C}^2\text{H}^5\text{O} = (\text{CH}^3)^2\text{O}$. (Dumas and Peligot, Ann. Ch. Phys. [2] lviii. 19.)—Produced by heating a mixture of 1 pt. wood-spirit and 2 pts. strong sulphuric acid, and washing the gaseous product with potash-lye. At ordinary temperatures, it is a gas having a pleasant ethereal odour, very soluble in alcohol, ether, and sulphuric acid, less soluble in water (which dissolves 37 times its volume of the gas at 18°). By cooling to -36° , by means of a mixture of snow and chloride of calcium, it is condensed to a liquid boiling at -20° . (Berthelot.)

Methylic ether unites directly with sulphuric anhydride, forming neutral methylic sulphate, $(\text{CH}^3)^2\text{O.SO}^3$ or $(\text{CH}^3)^2\text{SO}^4$.

METHYL, PLUMBIDES OF. See LEAD-RADICLES, ORGANIC (p. 563).

METHYL, SELENIDE OF. *Selenomethyl.* $\text{C}^2\text{H}^5\text{Se} = (\text{CH}^3)^2\text{Se}$. (Wöhler and Dean, Ann. Ch. Pharm. xcvi. 5).—Obtained by distilling a solution of methylsulphate of barium with selenide of potassium. It is a reddish-yellow very mobile liquid heavier than water, insoluble therein; of intensely disagreeable odour; very inflammable, and burning with a bluish flame. Strong nitric acid dissolves it, with rise of temperature; the solution is not precipitated by hydrochloric acid, but sulphurous acid throws down selenide of methyl from it. On attempting to concentrate the liquid by evaporation,

a new and very violent reaction is set up, nitric oxide being evolved, and the temperature sometimes rising so high as to set fire to the mixture.

The product of this reaction is methyl-selenious acid, CH_3SeO_2 , which, by cautious evaporation and cooling, may be obtained as a crystalline mass. It forms salts with bases, and is converted by hydrochloric acid into methyl-selenious chloride, $\text{CH}_3\text{SeO}_2\text{Cl} \cdot \text{H}_2\text{O}$, which crystallises in transparent prisms, and is converted by hydrobromic and hydriodic acid into the corresponding bromine- and iodine-compounds.

METHYL SULPHIDES OF. Methyl forms three sulphides, represented by the formulae $(\text{CH}_3)_2\text{S}$, $(\text{CH}_3)_2\text{S}^2$ and $(\text{CH}_3)_2\text{S}^3$, and a sulphhydrate or mercaptan, CH_3S , homologous with ethyl-mercaptan.

Protosulphide of Methyl. $\text{C}^2\text{H}_5\text{S} = (\text{CH}_3)_2\text{S}$. (Regnault, Ann. Ch. Phys. [2] lxxi. 391.)—This compound is easily obtained by passing gaseous chloride of methyl into a solution of protosulphide of potassium in wood-spirit contained in a tubulated retort. The gas is absorbed in large quantity, and if the retort be then heated and the receiver kept cool, sulphide of methyl distils over. It is a colourless, very mobile liquid, having an extremely disagreeable odour. Specific gravity, 0.845 at 21° . Boiling point 41° . Vapour-density 2.115. It is readily attacked by *chlorine*. On letting a few drops of it fall into a bottle filled with dry chlorine, a red flame is produced, and a large quantity of hydrochloric acid is obtained, together with a deposit of charcoal; but if the temperature be kept low, the following substitution-products are obtained:

a. Monochlorinated methylic sulphide, $(\text{CH}_2\text{Cl})\text{S}$. This is the product of the action of chlorine on sulphide of methyl, at a low temperature and under the influence of diffused daylight. It is a yellow oil, heavier than water, and having a very offensive odour. When heated in a retort, part of it distils over, but a considerable portion suffers alteration and leaves a carbonaceous residue. (Riche, Ann. Ch. Phys. [3] xliii. 283.)

B. Dichlorinated methylic sulphide, $(\text{CHCl}_2)_2\text{S}$. Produced by exposing the preceding compound to the action of chlorine, taking care to cool the vessel at the beginning to prevent the action from becoming too violent. It is a heavy yellow liquid, partly decomposed by distillation. (Riche.)

γ. Trichlorinated methylic sulphide, $(\text{CCl}_3)_2\text{S}$, is the product of the action of chlorine on the dichlorinated compound under the influence of direct sunshine. It is a limpid, amber-coloured liquid, having a strong penetrating odour. It boils regularly and without alteration between 156° and 160° . Its observed vapour-density is 5.68; the formula CCl_3S gives 9.41 for a condensation to 2 volumes, and 4.7 for a condensation to 4 volumes, indicating dissociation (1.469); but the specimen operated upon was probably impure. The compound is quite insoluble in water, but dissolves easily in alcohol and ether. It does not appear to be altered by aqueous potash.

The crude liquid resulting from the action of chlorine on dichlorinated methylic sulphide, has a red colour and contains chloride of sulphur and tetrachloride of carbon, which pass over with the first portions of the distillate, and are more abundant in proportion as the dichlorinated sulphide was less completely dried. (Riche.)

Protosulphide of methyl unites, like sulphide of ethyl (ii. 545), with *mercuric chloride* and *platinic chloride*, forming the compounds $\text{C}^2\text{H}_5\text{S} \cdot \text{Hg}^2\text{Cl}^2$ and $2\text{C}^2\text{H}_5\text{S} \cdot \text{PtCl}_4$, both of which are crystalline.

Disulphide of Methyl. CH_3S or $\text{C}^2\text{H}_5\text{S}^2$. (Cahours, Ann. Ch. Phys. [3] xviii. 157.)—Prepared, 1. By passing gaseous chloride of methyl through an alcoholic solution of disulphide of potassium.—2. By distilling a mixture of sulphomethylate of calcium and disulphide of potassium:

The yellowish distillate is rectified: and the portion which distils over between 110° and 112° is dried by chloride of calcium, and again partially distilled.

It is a transparent colourless liquid, having great refracting power, and a density of 1.046 at 18° . Boils between 116° and 118° . Vapour-density at $196^\circ = 3.298$. Has a very persistent and intolerable odour of onions.

It is but very sparingly soluble in *water*, but nevertheless imparts its odour to that liquid. Mixes in all proportions with *alcohol* and *ether*. (Cahours.)

This compound may be set on fire by a red-hot body, and burns with a blue flame, emitting a strong odour of sulphurous acid. *Chlorine* acts violently upon it, producing at first a substance which crystallises in amber-coloured rhombic tables, and is converted, by the further action of the chlorine, into a yellow, and ultimately into a red liquid, consisting of a mixture of $\text{C}^2\text{Cl}_3\text{S}$ and SCl_2 . *Bromine* likewise forms substitution-products. Moderately strong *nitric acid* acts strongly on the compound, producing sulphuric acid, and a peculiar acid which forms with potash long slender needles; with baryta, shining colourless tables; and with lime and oxide of lead, soluble

crystallisable salts.* *Sulphuric acid* dissolves the compound at ordinary temperatures; but decomposes it when heated. The compound is not altered by distillation over concentrated *potash-solution*.

Trisulphide of Methyl. $(\text{CH}^3)_2\text{S}^2$.—If the disulphide of potassium in the preceding preparation is replaced by pentasulphide, a considerable quantity of methylic disulphide is likewise obtained, but at the end of the distillation, at about 200° , a yellowish product is obtained having the composition of the trisulphide. It behaves like the disulphide with chlorine and with nitric acid. (Cahours.)

METHYL, SULPHYDRATE OF. $\text{CH}^3\text{S} = \begin{matrix} \text{CH}^3 \\ | \\ \text{H} \end{matrix} \text{S}$. (Gregory, Ann. Ch. Pharm. xv. 239.)—Formed by distilling in the water-bath, with efficient condensation, a mixture of 1 pt. of a solution of sulphomethylate of calcium, and 1 pt. of a solution of sulphydrate of calcium (both solutions having a density of 1.25), and agitating the distillate with caustic potash, to free it from sulphydric acid:

It is a liquid lighter than water, boiling at 21° , and having the odour of mercaptan, but even more offensive. It is slightly soluble in water; forms with *acetate of lead* a yellow, and with *mercuric oxide* a white compound $(\text{CH}^3\text{Hg}^2\text{S})$, which crystallises from a hot alcoholic solution in shining laminae not fusible at 100° .

METHYL, TELLURIDE OF. *Telluro-methyl.* $\text{C}^2\text{H}^6\text{Te} = (\text{CH}^3)_2\text{Te}$. (Wöhler and Dean, Ann. Ch. Pharm. xciii. 233.—Heeren, *Ueber Telluräthyl- und Tellurmethylverbindungen*, Göttingen, 1861.)—This compound is obtained by distilling telluride of potassium with sulphomethylate of barium, the distillation being continued as long as drops of oily liquid pass over with the water, and the process conducted altogether as for the preparation of tellurethyl (ii. 550).

Properties.—Telluromethyl is a pale yellow mobile liquid, which sinks in water, and does not mix with it. It boils at 82° , forming a yellow vapour like tellurium itself. It has an extremely disagreeable alliaceous odour, which is so intense and persistent, that even the breath is affected by it after some time. It fumes in the air from oxidation. When set on fire, it burns with a bright bluish-white flame, diffusing white fumes of tellurous acid. Strong nitric acid oxidises it, with evolution of nitric oxide.

Telluromethyl behaves to oxygen, chlorine and other chlorous radicles, like a metal, forming a basylous oxide and a series of salts, which are produced by saturating the solution of the oxide with acids, or by precipitation.

Acetate of Telluromethyl, $(\text{Me}^2\text{Te})'' \left\{ \begin{matrix} \text{C}^2\text{H}^3\text{O}^2 \\ \text{HO} \end{matrix} \right\}$, forms large, well-developed, limpid cubes, which have an unpleasant odour, crumble to a white amorphous powder when exposed to the air, are insoluble in cold alcohol, but dissolve easily in water. The solution is neutral, gives with sulphurous acid a yellow precipitate of telluromethyl; with hydrochloric acid, a white precipitate of the chloride; with iodide of potassium, no precipitate. (Heeren.)

The *bromide*, $(\text{CH}^3)_2\text{TeCl}^2$ or Me^2TeCl^2 , is obtained as a thick white precipitate, resembling bromide or chloride of lead, on adding hydrobromic acid to a solution of nitrate of telluromethyl. It forms shining colourless prisms which melt at 89° . (Wöhler and Dean.)

The *carbonate*, $(\text{Me}^2\text{Te})'' \left\{ \begin{matrix} (\text{CO}^2)'' \\ (\text{HO})^2 \end{matrix} \right\}$, is difficult to crystallise. (Heeren.)

The *chloride*, Me^2TeCl^2 , is obtained, on adding hydrochloric acid to a solution of the nitrate, as a thick white precipitate resembling chloride of lead (Wöhler and Dean); as a colourless heavy oil, which solidifies crystalline on cooling; similarly by adding hydrochloric acid to a solution of the oxychloride. (Heeren.)

It redissolves when heated, and crystallises on cooling in long thin prisms, like corrosive sublimate. It appears to be isomorphous with the bromide (Wöhler and Dean). It melts at 97.5° , but appears not to be volatile without decomposition. Solidifies from fusion in a mass having a highly crystalline structure. Does not distil over with water, but its heated aqueous solution has a faint alliaceous odour. Does not form any precipitate with platinum chloride. Dissolves readily in alcohol.

The *formate*, $(\text{Me}^2\text{Te})'' \left\{ \begin{matrix} \text{CHO}^2 \\ \text{HO} \end{matrix} \right\}$, crystallises in deliquescent colourless needles, forming a neutral solution in water, from which hydrochloric acid precipitates chloride of telluromethyl in the form of a colourless oil. (Heeren.)

* Muspratt (Chem. Soc. Qu. J. i. 53) gave to this acid the name of *Bisulphimethylic acid*, representing its salts by the formula $\text{C}^2\text{H}^3\text{MS}^2\text{O}^2$; more recently, however (Chem. Soc. Qu. J. iii. 22), he has found that it is identical with methyl-sulphurous acid, the formula of whose salts is $\text{C}^2\text{H}^3\text{MS}^2\text{O}^2$, or CH^3MSO^2 .

Iodide, Me^2TeS^2 .—When colourless hydriodic acid, or iodide of potassium, is dropped into a solution of nitrate of telluromethyl, a precipitate is formed of a bright lemon-yellow colour, but changing in a few seconds to vermilion-red. If the solutions are mixed warm, the precipitate exhibits at once a red colour and crystalline structure. When dry, it forms a vermilion coloured powder. The compound dissolves sparingly in cold, much more freely in hot water, and abundantly in hot alcohol, forming a reddish-yellow solution. From both solutions, it crystallises in small shining, vermilion-coloured prisms, which are largest when they separate from the alcoholic solution. They yield an orange-yellow powder. Under the microscope they appear orange-yellow by transmitted light, but certain faces exhibit a fine blue surface-colour. The salt appears to be dimorphous, like iodide of mercury; for on mixing the cooled alcoholic solution with about an equal volume of water, the iodide is precipitated, of a lemon-yellow colour; but in a few minutes a movement of the particles is observed throughout the liquid, and the precipitate soon assumes the character of vermilion-coloured crystalline laminae. The yellow variety cannot, however, be obtained in a permanent form; for the alcoholic solution yields red crystals by evaporation, and the compound cannot be melted without decomposition. Even at 130° , it is converted into black iodide of tellurium. (Wöhler and Dean.)

Nitrate, $\text{Me}^2\text{Te}(\text{NO}^2)^2$ (Wöhler and Dean); $\text{Me}^2\text{Te} \begin{Bmatrix} \text{NO}^2 \\ \text{HO} \end{Bmatrix}$ (Heeren).—Telluromethyl heated with moderately strong nitric acid, dissolves partially at first, with reddish-yellow colour; but after a while, a violent reaction ensues, attended with evolution of nitric oxide, and a colourless solution of the nitrate is obtained, which by careful evaporation, yields the salt in large colourless prisms. Sometimes, however, probably when the acid is too strong or in too great excess, the salt is obtained on evaporation, not in crystals, but in the form of a transparent amorphous mass containing tellurous acid, mixed or combined, and arising probably from decomposition of a portion of the telluromethyl. The nitrate decomposes with explosion when heated. It dissolves readily in water and alcohol. The aqueous solution, mixed with hydriodic, hydrobromic or hydrochloric acid, yields a precipitate of iodide, bromide or chloride of telluromethyl. (Wöhler and Dean.)

The oxalate, $(\text{Me}^2\text{Te})_2 \begin{Bmatrix} (\text{C}^2\text{O}^4)^2 \\ (\text{HO})^2 \end{Bmatrix}$, crystallises in monometric forms; it is neutral and less soluble in water than in alcohol; the aqueous solutions give with hydrochloric acid a precipitate of the chloride. (Heeren.)

Oxide of Telluromethyl, Me^2TeO , is obtained by decomposing the chloride or iodide with oxide of silver. Either of these compounds is moistened with water, and oxide of silver, recently precipitated by baryta-water and well washed, is added in excess, whereupon decomposition begins immediately, and the mass becomes spontaneously heated. The filtrate contains the oxide in solution.

Oxide of telluromethyl is indistinctly crystalline when dry; has an abominable taste, but is inodorous; deliquesces in the air like potash, and absorbs carbonic acid. Its aqueous solution is strongly alkaline to test-paper; eliminates ammonia from sal-ammoniac, even at ordinary temperatures, and forms a blue precipitate with sulphate of copper. Sulphurous acid added to the solution immediately throws down telluromethyl, in the form of a stinking oily liquid; hydrochloric acid precipitates the white chloride; hydriodic acid the red iodide. On saturating the aqueous oxide with sulphuric acid, a slight milky turbidity is produced; and on distilling the liquid, white sulphur separates out, and a yellow oil passes over, which appears to be merely reduced telluromethyl (Wöhler and Dean).—Heeren did not succeed in preparing the oxide in the solid state; the strongly alkaline solution obtained by decomposing the oxychloride with recently precipitated silver-oxide, quickly became turbid, and when evaporated in a vacuum, left nothing but tellurium.

The oxychloride, $(\text{Me}^2\text{Te})^2\text{Cl}^2\text{O}$, is formed by dissolving the chloride in ammonia. On evaporating and digesting the residue of sal-ammoniac and oxychloride in alcohol, the latter dissolves and separates from the solution in short colourless prisms. Hydrochloric acid added to the solution precipitates the chloride. (Wöhler and Dean.)

The oxybromide, $(\text{Me}^2\text{Te})^2\text{Br}^2\text{O}$, is obtained in a similar manner.

Phosphate.—On dropping phosphoric acid into a solution of the oxide, a lemon-yellow precipitate of telluromethyl phosphate is produced, insoluble in water and in alcohol; it turns grey when exposed to light, and melts when heated to a brown substance (Tel^2P ?). It dissolves in excess of phosphoric acid, forming a colourless liquid, which yields colourless crystals by evaporation. From the aqueous solution of these crystals, ammonia throws down the yellow insoluble phosphate, and hydrochloric acid the white chloride. (Heeren.)

The *sulphate*, $(\text{Me}^s\text{Te})_2\left\{\begin{smallmatrix} \text{SO}^4 \\ (\text{HO})^2 \end{smallmatrix}\right.$ (Heeren), is obtained by saturating the base with sulphuric acid, or by decomposing the solution of the oxychloride with sulphate of silver. It crystallises in large, very regular transparent cubes, easily soluble in water, insoluble in alcohol.

Sulphochloride, $(\text{Me}^s\text{Te}^s)\text{ClS}^?$ Sulphuric acid passed through a solution of the chloride, forms a white flocculent precipitate which afterwards turns yellowish, the liquid at the same time acquiring an extremely repulsive odour. If it be then distilled, there passes over with the water a heavy oily liquid, having a reddish-yellow colour and extremely offensive odour, and yielding sulphuric acid when oxidised with nitromuriatic acid. (Wöhler and Dönn.)

According to Heeren, sulphydric acid forms, in solutions of telluromethyl salts, an orange-yellow precipitate, which, when heated or strongly ignited, cakes together, and sinks to the bottom in the form of black heavy oily drops, from which ether extracts telluromethyl, leaving a black powder consisting of disulphide of tellurium.

METHYLACETAL. See METHYLATE OF ETHYLENE.

METHYLACETONE. See ACETONE (i. 31).

METHYLAL. $\text{C}^s\text{H}^s\text{O}^2$.—A product of the oxidation of methyl alcohol. When a mixture of wood-spirit, sulphuric acid, and peroxide of manganese is distilled, there passes over, amongst other products, an ethereal liquid, miscible with water, to which Dumas (Ann. Ch. Pharm. xxvii. 135) gave the name formomethylal, regarding it as a definite compound. Malaguti, however (Ann. Ch. Phys. [2] lxx. 390), showed that it is a mixture of methyl formate and methylal, of variable composition and boiling point, and is resolved by boiling with potash into formic acid, methyl alcohol, and methylal.

Methylal is a limpid liquid smelling like acetic acid, of specific gravity 0.8551, boiling at 42° under a pressure of 0.761 met.; its vapour-density is 2.625. It dissolves in 3 volumes of water, and is separated therefrom by potash; soluble also in alcohol and ether. When gently heated with slightly diluted nitric acid, it decomposes, eliminating nitric oxide, without carbonic anhydride or carbonic oxide, and yielding a solution containing a considerable quantity of formic acid. It is likewise oxidised to formic acid by a mixture of sulphuric acid and chromate of potassium, and by alcoholic potash.—Chlorine acts very slowly on it, producing formic acid and trichloride of carbon:

METHYLAMINES AND METHYLAMMONIUMS. Organic bases homologous with the ethylamines, formed on the types NH^3 and NH^4 respectively, by the partial or total substitution of methyl for hydrogen; viz. methylamine, $\text{N.H}^3.\text{CH}^3$; dimethylamine, $\text{N.H}^2.(\text{CH}^3)^2$; trimethylamine, $\text{N}^3.(\text{CH}^3)^3$ and tetramethylammonium, $\text{N}^4.(\text{CH}^3)^4$. The methylamines, like the ethylamines, are known in the free state; but tetramethylammonium is known only in its salts, which are analogous in constitution to the ammonium salts. There are also amines and ammoniums in which the hydrogen is replaced, partly by methyl, partly by other alcohol-radicles, as ethyl, amyl, phenyl, &c., e.g. methyl-ethyl-amylamine, $\text{N}^3.\text{CH}^3.\text{C}^2\text{H}^5.\text{C}^4\text{H}^9$; methyl-triethyl-ammonium, $\text{N}^4.\text{CH}^3.(\text{C}^2\text{H}^5)^3$.

METHYLAMINE. $\text{CH}^3\text{N} = \begin{matrix} \text{H} \\ | \\ \text{N} \end{matrix} \left\{ \begin{matrix} \text{H} \\ | \\ \text{CH}^3 \end{matrix} \right.$ *Methylammonia, Methylia.*—This base

was discovered and fully examined by Wurtz in 1849 (Compt. rend. xxviii. 223 and 323; Ann. Ch. Phys. [3] xxx. 443). It is produced by reactions analogous to those which give rise to the formation of ethylamine (ii. 553); viz. 1. By the action of potash on cyanate or cyanurate of methyl (Wurtz).—2. By the action of potash on methyl-carbamide (methyl-urea) (Wurtz).—3. In the form of a salt, by the action of ammonia on various methyl ethers: thus iodide of methyl heated in a sealed tube with ammonia, yields hydriodate of methylamine or iodide of methylammonium, together with iodide of ammonium and the iodides of di-, tri-, and tetra-methylammonium (Hofmann).—4. By heating chloride or iodide of ammonium with wood-spirit in sealed tubes (Berthelot).—5. By the action of caustic alkalis on morphine and codeine (Wertheim, Ann. Ch. Pharm. lxxiii. 210), and by heating glycocine with anhydrous baryta (Cahours, ii. 903):

6. In combination with hydrochloric acid, by the action of chlorine on theobromine (Rochleder and Hlasiwetz, Jahresb. 1850, p. 437) or on caffeine (Rochleder, *ibid.* 434).—7. By the action of nascent hydrogen on hydrocyanic acid: $\text{CHN} + \text{H}^+ = \text{CH}^3\text{N}$ (Mendius, Ann. Ch. Pharm. cxii. 129).—9. Methylamine occurs in bone-oil

(Anderson, Jahresb. 1851, p. 476), and in small quantity among the products of the distillation of crude acetate (pyrolignite) of calcium. (C. G. Williams, *ibid.* 1853, p. 467.)

Preparation. 1. *By the action of potash on Cyanurate of Methyl.*—The cyanurate is heated with potash-ley in a flask surmounted with a worm-tube, to condense the aqueous vapours and separate the methylamine, which then passes on into a receiver containing a small quantity of pure water, which dissolves it. The decomposition of the methyl-cyanuric ether by potash-ley, which is very slow, may be accelerated by first melting the ether with solid potash mixed with a small quantity of water. The aqueous solution of methylamine in the receiver is saturated with hydrochloric acid and evaporated to dryness. (Wurtz.)

2. *By the action of Nascent Hydrogen on Hydrocyanic acid.* Mendius mixes the hydrocyanic acid with hydrochloric acid and alcohol, adds granulated zinc, and when the action is ended, distills off about half the liquid, and again subjects the distillate, which contains a considerable quantity of unaltered prussic acid, to the action of the zinc. By repeating this treatment a certain number of times, a solution is ultimately obtained containing hydrochlorate of methylamine mixed with chloride of zinc; and this solution distilled with lime or potash, yields free methylamine, which may be condensed in water and combined with hydrochloric acid as before. Debus (Chem. Soc. J. xvi, 249) effects the combination of the hydrogen with the prussic acid by means of platinum-black. A stream of hydrogen is passed through a mixture of 16 grms. cyanide of potassium, 15 grms. sulphuric acid, and 5 oz. water, contained in a retort, and then conducted successively through an empty vessel, a tube containing fused chloride of calcium, a tube containing platinum-black and immersed in a paraffin bath heated to 110°, and, finally, through a Liebig's bulb-apparatus filled with dilute hydrochloric acid. As soon as the mixture of prussic acid and hydrogen comes in contact with the platinum-black, dense white clouds of hydrochlorate of methylamine become perceptible, filling the apparatus from the platinum to the acid. The prussic acid mixture is gradually heated to the boiling point, and kept at that temperature, with a current of hydrogen continually passing through it, till the process is completed. The acid liquid in the bulbs, when evaporated on the water-bath, leaves a white residue almost wholly soluble in alcohol, and the alcoholic solution leaves on evaporation a colourless crystalline mass of hydrochlorate of methylamine. Part of the methylamine produced in this reaction unites with the hydrocyanic acid, forming cyanide of methylammonium, and this acts on the platinum in such a manner as to form a double cyanide of platinum and methylammonium (p. 997), which surrounds the particles of the platinum-black, and after a while prevents further action. If its formation could be prevented, this method would doubtless afford the readiest means of preparing methylamine.

To prepare pure methylamine, the hydrochlorate, perfectly dried, is mixed with twice its weight of quicklime, and the mixture introduced into a long tube closed at one end, in such quantity as to half fill it, the other half being filled with fragments of potassium-hydrate. From this tube a gas-delivery tube passes to the mercurial trough. On applying a gentle heat to the tube, beginning at the closed end, the gas is disengaged, and may be collected over the mercury.

Properties.—Methylamine is a colourless gas, having a strong ammoniacal odour. Like ammonia, it turns reddened litmus-paper blue; fumes strongly with hydrochloric acid; combines with its own volume of that gas, and half its volume of carbonic anhydride; is rapidly absorbed by water, and also by charcoal. It is distinguished from ammonia by taking fire when brought in contact with a lighted taper; it then burns with a livid yellowish flame, producing water, carbonic anhydride, and nitrogen, mixed, if the combustion be incomplete, with cyanogen and hydrocyanic acid. Specific gravity 1.13 at 25°, and 1.08 at 43°. When cooled a few degrees below 0°, it condenses to a very mobile liquid, which does not solidify in a mixture of solid carbonic acid and ether. (Wurtz.)

Methylamine is the most soluble in water of all known gases. Water at 25° absorbs 959 times, and at 12.5°, 1150 times its volume of the gas. The solution has the powerful odour of the gas, and is extremely caustic; it gives off the gas when boiled. It is decomposed by iodine, bromine, and chlorine. Iodine added to it, not in excess, forms hydriodate of methylamine which dissolves, and diiodomethylamine, $C(H^2P)N$, which remains undissolved:

Bromine and chlorine appear to act in a similar manner.

The action of aqueous methylamine on metallic salts is, for the most part, similar to that of ammonia. The salts of magnesium, manganese, iron, bismuth, chromium, uranium, and tin are precipitated by methylamine in the same manner as by ammonia. With zinc-salts methylamine forms a white precipitate, soluble in a large excess of

the reagent. With *copper-salts*, a bluish-white precipitate, easily soluble in excess, and forming a deep blue solution. With *cadmium-salts*, a white precipitate, insoluble in excess. With *nickel- and cobalt-salts*, also, it forms precipitates insoluble in excess. These last three reactions differ from those produced by ammonia. *Acetate of lead* is scarcely clouded by methylamine, but the *nitrate* is completely precipitated. With *mercurous salts*, methylamine, like ammonia, forms a black precipitate; with *mercuric chloride*, a white, flocculent precipitate, insoluble in excess. *Nitrate of silver* is completely precipitated by methylamine; and the oxide, whether precipitated by the alkali itself or by potash, dissolves readily in excess of the former. The solution, abandoned to spontaneous evaporation, deposits a black substance, which contains carbon, hydrogen, nitrogen, and silver, and is probably the analogue of fulminating silver; but does not explode either by heat or by percussion. *Chloride of silver* is also dissolved by aqueous methylamine. With *trichloride of gold*, methylamine forms a brownish-yellow precipitate, which dissolves readily in an excess of the precipitant, forming an orange-red solution. A concentrated solution of *platinic chloride* forms with methylamine a crystalline precipitate, consisting of chloroplatinate of methylamine, in the form of orange-yellow scales. The formation of this precipitate is prevented, even by slight dilution. (Wurtz.)

Decompositions.—1. Methylamine passed through a red-hot porcelain tube, filled with fragments of porcelain, is completely decomposed into free hydrogen, marsh-gas, ammonia, and hydrocyanic acid:

If the gaseous mixture, as it issues from the tube, be passed through water, and then collected in jars over mercury, the water acquires an alkaline reaction, and is found to contain hydrocyanate of ammonia, and the gas in the jars consists, in 100 measures, of 13.77 vol. hydrocyanic acid, 71.08 hydrogen, and 14.37 marsh-gas.

2. Two vol. methylamine exploded with $4\frac{1}{2}$ vol. oxygen produce 2 vol. CO^2 and 1 vol. N. Now 2 vol. CO^2 contain 2 vol. or 2 at. O, and therefore 1 at. C; and the remaining $2\frac{1}{2}$ vol. O must have been consumed in burning the hydrogen, which therefore amounts to 5 vol. Hence, since the volumes of elementary gases are as the numbers of atoms contained in them, it follows that 1 molecule (= 2 vol.) of methylamine contains 1 at. carbon, 5 at. hydrogen, and 1 at. nitrogen, that is to say its formula is CH^3N . To obtain complete combustion, it is necessary to mix the gas with 3 times its volume of dry oxygen, and to add to the mixture, according to Regnault's recommendation, a certain quantity of detonating gas, derived from the electrolysis of water, also perfectly dry. (Wurtz, Ann. Ch. Phys. [3] xxx. 451.)

3. *Potassium* heated in the gas decomposes it completely, yielding free hydrogen and cyanide of potassium: $\text{CH}^3\text{N} + \text{K} = \text{CNK} + \text{H}^2$, 31.5 vol. methylamine yielding 81.5 vol. pure hydrogen, numbers which are nearly in the ratio of 2 : 5. The action, however, exhibits two stages. At first, while the heat is moderate, the volume of gas increases but little, and the residue probably contains $\text{C}(\text{H}^3\text{K})\text{N}$, a compound analogous to amide of potassium; and this, at a higher temperature, is resolved into hydrogen and cyanide of potassium, the latter decomposition being accompanied by the considerable increase in volume which is observed. (Wurtz.)

4. With gaseous *chloride of cyanogen*, it forms hydrochlorate of methylamine, and cyanomethylamide (Cahours and Cloez, Compt. rend. xxxviii. 364)

METHYLAMINE-SALTS.—Methylamine is a strong base, neutralising acids completely, forming well-defined crystalline salts, and precipitating metallic oxides from their solutions (p. 995). Its salts, like those of ethylamine, may be regarded as compounds of methylamine with acids, or of methylammonium with the radicles of the same acids, *e. g.*:

Methylamine-salts are soluble in water, and most of them also in alcohol; the latter property affords a means of separating them from ammonium-salts, when the two occur together. They are decomposed by heating with fixed alkalis, giving off gaseous methylamine.

Bromhydrate or Hydrobromate of Methylamine, CH^3NBr , is obtained by the action of bromine on aqueous methylamine. It is very soluble in water and in alcohol, and crystallises from the alcoholic solution in large shining plates having an anisotropic aspect and very deliquescent.

Carbonate. $(\text{CH}_3\text{N})_2\text{CO}_3$.—This salt is prepared by distilling the fused hydrochlorate with carbonate of calcium. The product of the distillation is a very thick liquid, having a quantity of solid matter in the middle: the liquid is a highly concentrated solution of carbonate of methylamine; the solid is methyl-carbamic acid. On gently heating the contents of the receiver, the methyl-carbamic acid partly dissolves and partly volatilises. The liquid portion, as it cools, deposits crystals of the carbonate, which is highly deliquescent and volatilises even at ordinary temperatures. It is difficult, however, to obtain this salt free from methyl-carbamic acid.

Gaseous methylamine unites with its own volume of carbonic anhydride, forming methyl-carbamic acid (the so-called anhydrous carbonate of methylamine),

- **Chlorhydrate or Hydrochlorate of Methylamine.** *Chloride of Methylammonium.* $\text{CH}_3\text{N}.\text{Cl}$.—Gaseous methylamine unites with its own volume of hydrochloric acid gas, forming a white solid salt, which adheres like sal-ammoniac to the sides of the vessel.—The salt is prepared by saturating aqueous methylamine with hydrochloric acid, and evaporating to dryness. The residue dissolves easily in boiling alcohol, and crystallises on cooling in fine, large laminae, which, at the moment of their formation, appear iridescent by reflected light. It is deliquescent; does not fuse till heated above 100° . Heated in an open vessel to a very high temperature, it volatilises in very dense vapours, which condense to a white powder on the surface of cold bodies (Wurtz). When a solution of this salt, either in water or in alcohol, is treated with amalgam of potassium, hydrogen is evolved, and the liquid becomes alkaline. Wurtz did not succeed in obtaining by this reaction an amalgam of methylammonium corresponding to the *ammoniacal amalgam* (i. 186). Neither is such a compound produced by placing mercury in a cavity in a lump of hydrochlorate of methylamine, and connecting it with the voltaic battery.

Chloro-aurate. $\text{CH}_3\text{NCl}.\text{AuCl}_3$.—On mixing a solution of hydrochlorate of methylamine with a solution of trichloride of gold, no precipitate is formed; but on evaporating till the liquid becomes very concentrated and then leaving it to cool, the double salt is obtained in splendid golden-yellow needles, soluble in water, alcohol, and ether.

Chloromercurate. $2\text{CH}_3\text{NCl}.\text{Hg}^2\text{Cl}_2$.—Formed by evaporating a mixture of 1 at. hydrochlorate of methylamine and 1 at. corrosive sublimate. The solution, when highly concentrated, yields bulky crystals of the double salt.

Chloroplatinate, $2\text{CH}_3\text{NCl}.\text{PtCl}_4$.—Beautiful golden-yellow scales which are insoluble in alcohol, but dissolve in boiling water and crystallise on cooling. When heated, they blacken, emitting very copious fumes and leaving a residue of platinum mixed with charcoal, which burns in the air.

For the compounds of methylamine with platinous chloride, see PLATINUM-SALTS.

Sulphate.—Very soluble in water, insoluble in alcohol, uncrystallisable. When evaporated with cyanate of potassium, it yields methyl-carbamide, $\text{N}^2.\text{H}^2.\text{CH}_3.\text{CO}^2$.

Cyanide of Methylammonium and Platinum, $(\text{CH}_3\text{N})_2\text{PtCy}_4$.—Formed in the preparation of methylamine by passing a mixture of hydrogen and hydrocyanic acid vapour over heated platinum-black (p. 995). Part of the methylamine formed unites with the hydrocyanic acid, and the cyanide of methylammonium thus formed acts on the platinum in the manner represented by the equation—

On washing the platinum-black with water, concentrating the solution over the water-bath, and then leaving it over oil of vitriol, the double cyanide separates in long prismatic crystals having a slight brown tint. They are easily soluble in water, and leave a grey residue of platinum when strongly heated in the air. (Debus.)

Iodhydrate or Hydriodate, CH_3NI .—Produced, together with diiodomethylamine by the action of iodine on aqueous methylamine.

Nitrate, $\text{CH}_3\text{N}.\text{NO}^2$.—Formed by saturating aqueous methylamine with nitric acid. The solution, when evaporated, yields beautiful, right rhomboidal prisms, very much elongated, and closely resembling the crystals of nitrate of ammonium. They are deliquescent, and dissolve very readily in water and alcohol. They are decomposed by distillation, yielding gaseous products, and drops of an oily liquid insoluble in water.

DIIODOMETHYLAMINE, $\text{C}(\text{H}^2\text{I}^2)\text{N}$. This base, formed by the action of iodine on aqueous methylamine, is a garnet-coloured powder which dissolves in alcohol, but appears to be decomposed thereby. It is decomposed by heat, but does not explode like iodide of nitrogen. It is also decomposed by potash, with formation of iodide of potassium, a

volatile product having a very pungent odour, and a slight insoluble flocculent residue. (Wurtz, Ann. Ch. Phys. [3] xxx. 455.)

Dimethylamine, $C^2H^5N = N.H(CH^3)^2$. This base, isomeric with ethylamine, is produced, as a hydriodate, together with other similar compounds, by heating iodide of methyl with ammonia (Hofmann, p. 994). It is also formed by heating the so-called sulphite of aldehyde-ammonia (i. 108) in a sealed tube, or by decomposing it with lime (Petersen, Ann. Ch. Pharm. cii. 317):

Gössmann, who first noticed this decomposition (*ibid.* xci. 122), supposed that the resulting base was ethylamine; but Petersen has shown that by passing the evolved gas into iodide of ethyl, and heating the liquid in a sealed tube, iodide of dimethyl-diethyl-ammonium is produced:

The quantity of dimethylamine produced in this reaction is, however, very small, and Hofmann (Proc. Roy. Soc. xii. 380) finds that this base may be obtained with much greater facility by treating the mixture of the iodides of ammonium, methylammonium, &c., produced by the action of ammonia on iodide of methyl, with oxalate of ethyl, in the manner already described for the separation of the corresponding ethyl-bases (ii. 555, 558).

An alcoholic solution of ammonia gently heated with iodide of methyl in a flask provided with a condenser, solidifies into a crystalline mixture of the iodides of ammonium and of methyl-, dimethyl-, trimethyl-, and tetramethyl-ammonium. The more soluble iodides separated from the sparingly soluble iodide of tetramethylammonium are evaporated and distilled with potash; and the bases evolved, after being carefully dried by passing over hydrate of potassium, are made to pass through a powerfully refrigerated worm-tube, in which dimethylamine and trimethylamine, together with a portion of the methylamine, condense, the ammonia and the rest of the methylamine being carried off as gas and condensed in water. The mixture of the three methyl-bases is then treated with oxalate of ethyl, whereupon the methylamine immediately solidifies into a crystalline mass of dimethyloxamide, $N^2H^2(C^2O^2)^2(CI^3)^2$, and the dimethylamine is

converted into dimethyloxamate of ethyl, $\left. \begin{matrix} (CH^3)^2 \\ C^2O^2 \\ C^2H^5 \end{matrix} \right\} N$, a liquid boiling between

250° and 260°, while the trimethylamine remains unchanged and may be expelled by gently heating the mixture in a water-bath. The dimethyloxamate of ethyl is easily separated from the mixture by solution in cold water, and when distilled with hydrate of potassium, yields a mixture of alcohol and dimethylamine, oxalate of potassium remaining behind. The distillate evaporated with hydrochloric acid yields a crystallised residue of chloride of dimethylammonium, from which pure dimethylamine may be obtained by distillation with potash. (Hofmann.)

E. Lucius (Ann. Ch. Pharm. ciii. 105), by distilling guano with lime, obtained a small quantity of a base which he regarded as dimethylamine (from 28 lbs. guano, 0.5 gm. of a platinum-salt having the composition $2(C^2H^5NCl.PtCl^4)$).

Dimethylamine is a highly alkaline liquid having a strong ammoniacal odour, easily soluble in water, and boiling between 8° and 9°. Its *gold-salt*, $C^2H^5NCl.AuCl^4$, and *platinum-salt*, $2C^2H^5NCl.PtCl^4$, both crystallise well, the latter in long splendid needles, shooting through the liquid from one side of the vessel to the other. (Hofmann.)

Trimethylamine, $C^3H^7N = (CH^3)^3N$. Discovered by Hofmann (Chem. Soc. Qu. J. iv. 304). Produced, together with other methyl-bases, in combination with hydriodic acid, by the action of ammonia on iodide of methyl, and separated by treatment with oxalic ether and subsequent distillation, as described under DIMETHYLAMINE. It occurs ready formed in many organic substances, especially as a product of decomposition. Hofmann (Chem. Soc. Qu. J. v. 288) found it in herring-pickle. According to Dessaignes, it occurs in human urine (Ann. Ch. Pharm. c. 218), and in the blood of the calf, twelve hours after it has been taken from the animal, but not in the perfectly fresh blood (J. Pharm. [3] xxxii. 43; Jahresb. 1857, p. 382); in the flowers of *Crataegus oxyacantha* (Wicke, *ibid.* 1854, 478; 1862, p. 330), also of *Crataegus monogyna*, *Pyrus Aucuparia*, and *Pyrus communis* (Wittstein, *ibid.*); in the stinking goose-foot, *Chenopodium vulvaria* (Dessaignes, *ibid.* 1851, p. 479; Wittstein, Wicke); in *craw-fish* (Wittstein), and in ergot of rye (Wals, Jahresb. 1852, p. 552; Winckler, *ibid.* 553; Rithausen, Rép. chim. pur. 1863, p. 420). It has been found also in very small quantity in guano (Hesse, *ibid.* 1857, p. 402), in putrefying yeast, (A. Müller, *ibid.*), and in putrefying wheat-dough (Sullivan, *ibid.* 1858, p. 231). It is also produced by heating narcotine with potassium-hydrate to 260°—300° (Wertheim), or with water to 250°—260° (Reynoso), see NARCOTINE; probably also in the decomposition of codeine by potash-lime. (Anderson, Jahresb. 1850, p. 430.)

The trimethylamine obtained from several of these sources was formerly mistaken for tritylamine, $C^3H^3.H^3N$, with which it is isomeric.

Trimethylamine is an oily alkaline liquid having a strong odour of stale fish. It boils at 9° (Hofmann), which is but little above the boiling point of dimethylamine. When a rapid succession of electric sparks from an induction-coil is passed through the vapour, it is slowly decomposed, yielding a tarry deposit; but even a long continuance of the action does not suffice to set the whole of the nitrogen free. (Hofmann and Buff, Ann. Ch. Pharm. cxiii. 129.)

It unites with acids, forming crystallisable salts. The *sulphate* mixed with *sulphate of aluminium* forms large crystals of trimethylamine-alum, probably having the composition $\left. \begin{matrix} C^3H^3N \\ Al''' \end{matrix} \right\} (SO^4)^2.12H^2O$, analogous to that of ammonia-alum; they melt at 100° , and give off their water of crystallisation with intumescence at 120° . (Rockenschuss, Ann. Ch. Pharm. lxxxiii. 343.)

Trimethylamine unites directly with iodide of methyl, forming iodide of tetramethylammonium, $(CH^3)^4NI$, and with dibromide of ethylene, yielding the compound $C^2H^4NBr_2 = (CH^3)^2(C^2H^4Br)NBr$. (Hofmann, see p. 1000.)

Tetramethylammonium, $C^4H^{12}N = (CH^3)^4N$. (Hofmann, Phil. Trans. 1850, p. 93; Chem. Soc. Qu. J. iv. 321.) The iodide of this base is produced: 1. By the action of iodide of methyl on trimethylamine, the two liquids immediately uniting into a crystalline mass: $(CH^3)^3N + CH^3I = (CH^3)^4NI$.—2. By the action of ammonia on iodide of methyl. Of the five iodides, H^3NI , $(H^3Mc)NI$, $(H^3Me^2)NI$, $(HMe^3)NI$, and Me^4NI , produced by this reaction, the first and last are the most abundant; and when an alcoholic solution of ammonia is used, and the iodide of methyl is in excess, the action is completed in a few hours, the hot solution, as it cools, depositing crystals of iodide of tetramethylammonium, which may be purified by washing with cold water and recrystallisation from hot water.

Hydrate of Tetramethylammonium, $\left. \begin{matrix} (CH^3)^4N \\ II \end{matrix} \right\} O$, is obtained by digesting oxide of silver in the aqueous solution of the iodide. On filtering to separate iodide of silver, a strongly alkaline solution is obtained, which, when evaporated in vacuo over sulphuric acid, yields a white crystalline mass, resembling hydrate of potassium, and absorbing water and carbonic acid with avidity. When heated, it intumesces strongly, and is completely volatilised, yielding a strongly alkaline distillate. According to the decomposition-products obtained with other bodies of similar decomposition—hydrate of tetramethylammonium, for example (ii. 561), it might be expected to yield trimethylamine and methylene, CH^2 ; but it appears to be decomposed in a different manner, as not a trace of permanent gas is given off.

Neutralised with acids, it yields crystallisable salts. The *sulphate*, *oxalate*, *nitrate*, and *hydrochlorate* have been prepared. The *nitrate* crystallises in long shining needles; the *chloroplatinate*, $2(C^4H^{12}N)Cl.PtCl_4$, in well-defined octahedrons of a deep orange-yellow colour, partially decomposed by boiling with water, like the platinum-salts of many other ammonium-bases. (Hofmann.)

Iodides of Tetramethylammonium.—Tetramethylammonium unites with iodine in several proportions. **a.** The *mono-iodide*, $(CH^3)^4NI$, prepared as above, crystallises in hard flat needles of dazzling whiteness; sparingly soluble in cold, more soluble in boiling water. The solution is neutral and very bitter. The crystals are nearly insoluble in alcohol, quite insoluble in ether, sparingly soluble in an alkaline liquid. (Hofmann.)

b. An alcoholic solution of iodine added to a hot solution of the mono-iodide of tetramethylammonium, forms an abundant crop of shining crystals, consisting of the *penta-iodide*, $(CH^3)^5NI^2$. This compound is decomposed by boiling with water, yielding the mono-iodide and probably iodides containing larger proportions of iodine.—**γ.** On adding iodine to a boiling solution of the penta-iodide in dilute alcohol, a melted mass is formed at the bottom of the liquid, which on cooling solidifies to a crystalline mass consisting of the *deca-iodide*, $(CH^3)^{10}NI^4$.—**δ.** A solution of the mono-iodide mixed with an alcoholic solution of iodine containing as much iodine as is required to form the tri-iodide, yields at first crystals of the penta-iodide, afterwards a mixture of the tri- and penta-iodides, which may be separated mechanically and purified by recrystallisation. The *tri-iodide*, $(CH^3)^3NI^3$, forms rhombic crystals having a deep violet colour and strong lustre; it is more soluble in alcohol than the penta-iodide. (Weltzien, Ann. Ch. Pharm. xci. 41; xcix. 1).

Iodomercurates.—**a.** The salt, $(CH^3)^4NI.Hg^2I^2$, is obtained in small light yellow prisms moderately soluble in alcohol: 1. by adding mercuric iodide to an excess of iodide of tetramethylammonium in hot alcoholic solution; 2. by the action of metallic mercury on the tri-iodide of tetramethylammonium, or on the following salt.

A. $2(\text{CH}_3)_4\text{NI} \cdot 3\text{Hg}^{+}\text{I}_2^-$.—This compound is obtained in fine lemon-yellow waxy scales by adding a hot alcoholic solution of iodide of tetramethylammonium to an excess of mercuric iodide, or by the action of metallic mercury on penta-iodide of tetramethylammonium. (H. Bisse, Ann. Ch. Pharm. cvii. 223.)

Chloriodides.—A *tetrachloriodide*, $(\text{CH}_3)_4\text{NICl}_4$, analogous to Filhol's chloriodide of ammonium, NH_4ICl_4 , is obtained by heating the tri- or penta-iodide with oxide of silver; iodide of silver is then immediately formed (together with iodate), and a colourless strongly alkaline solution is formed, containing hydrate and iodate of tetramethylammonium:

and on gently heating the filtered liquid with hydrochloric acid (best after neutralising it with iodic acid), chlorine is evolved, and tetrachloriodide of tetramethylammonium is deposited, as a very loosely coherent, lemon-yellow substance, smelling strongly of iodine:

The *trichloriodide*, $(\text{CH}_3)_4\text{NICl}_3$, is obtained as a lemon-yellow substance: 1. By mixing chloride of tetramethylammonium with chloride of iodine. 2. By passing chlorine into a solution of the mono-iodide; a precipitate of the penta-iodide is then formed, and afterwards a colourless solution which yields the tri-iodide by evaporation.

The *dichloriodide*, $(\text{CH}_3)_4\text{NICl}_2$, is deposited from an aqueous solution of the trichloriodide in shining yellow inodorous crystals belonging to the dimetric system. (Weltzien, loc. cit.)

Methyl-bases containing Ethyl and Amyl.

a. Methyl-triethyl-ammonium. $(\text{CH}_3)(\text{C}_2\text{H}_5)_3\text{N}$.—The *mono-iodide* of this base, obtained by the action of methylic iodide on triethylamine, resembles the iodide of tetrethylammonium (ii. 562); it is very soluble in water, forming a neutral very bitter solution which is decomposed by potash, the iodide being precipitated without alteration.

The iodide decomposed by moist oxide of silver, yields the *hydrate* which dries up to a crystalline mass resembling hydrate of tetrethylammonium, and forming crystalline salts with sulphuric, hydrochloric, nitric, and oxalic acids. The *chloroplatinate* is a beautiful crystalline precipitate containing $2\text{Me}^+\text{E}^+\text{NCl.PtCl}_4^-$. (Hofmann, Chem. Soc. Qu. J. iv. 313.)

The *tri-iodide*, $\text{Me}^+\text{E}^+\text{NI}_3$, obtained in the manner described below for the corresponding compound of trimethyl-ethyl-ammonium, crystallises in bluish-violet quadrate laminae, dark reddish-yellow by transmitted light, melting at 62° . (R. Müller, Ann. Ch. Pharm. cviii. 1.)

B. Dimethyl-diethyl-ammonium. $(\text{CH}_3)_2(\text{C}_2\text{H}_5)_2\text{N}$.—The *iodide* obtained by passing the vapour of diethylamine into iodide of ethyl, and heating the resulting liquid to 100° in a sealed tube, forms white tabular crystals easily soluble in water and in alcohol. The *chloroplatinate*, $2\text{Me}^+\text{E}^+\text{NCl.PtCl}_4^-$, forms yellowish prisms or tablets moderately soluble in water, sparingly in alcohol and ether. (Petersen, Ann. Ch. Pharm. xci. 122.)

γ. Trimethyl-ethyl-ammonium. $(\text{CH}_3)_3(\text{C}_2\text{H}_5)\text{N}$.—The *mono-iodide* of this base is obtained by the direct union of trimethylamine with iodide of ethyl.

On adding 2 at. iodine to a warm alcoholic solution of 1 at. of this mono-iodide, and leaving the solution to cool, the *tri-iodide*, $\text{Me}^+\text{E}^+\text{NI}_3$, in very brittle, rhombic prisms, which are instantly resolved by water into the mono-iodide and the green penta-iodide: in alcoholic solution, on the other hand, these two compounds reunite and form the tri-iodide. The crystals of the latter are dark brown, or in thin splinters, brownish-yellow, and somewhat dichromatic; their surface-colour is bluish-violet; they melt at 64° without decomposition. (R. Müller, Ann. Ch. Pharm. cviii. 1.)

The *penta-iodide*, $\text{Me}^+\text{E}^+\text{NI}_5$, obtained by treating the mono- or tri-iodide in alcoholic solution with excess of iodine, or as above mentioned, by decomposing the tri-iodide with water, crystallises in quadrate laminae exhibiting the combination $\text{oP} : \infty\text{P} \infty : \text{P}$ (the latter faces very subordinate). Angle $\text{oP} : \text{P} = 141^\circ 0'$. The crystals are opaque with metallic lustre, yellowish in very thin layers when polished, yellowish-brown in thicker layers; surface colour, metallic green, becoming dark blue on exposure to the air; they melt at 68° . (R. Müller, loc. cit.)

METHYLAMMONIUMS—METHYLATE OF ETHYL. 1001

5. Trimethyl-bromethyl-ammonium. $C^3H^3BrN = (CH^3)^3(C^2H^2Br)N$.—The bromide of this base, $C^3H^3NBr^2 = [(CH^3)^3(C^2H^2Br)N]Br$, is produced by the action of aqueous or alcoholic trimethylamine on bromide of ethylene, best in sealed tubes at $40^\circ - 50^\circ$: $C^3H^3N + C^2H^2Br^2 = C^3H^3NBr^2$. It is very soluble in boiling alcohol, whence it crystallises in white needles, less soluble in cold alcohol, insoluble in ether. Nitrate of silver added to the solution of this salt, throws down only half the bromine; and the filtrate freed from excess of silver by hydrochloric acid, yields with platonic chloride, sparingly soluble octahedral crystals of the *chloroplatinate*, $2C^3H^3NBrCl.PtCl_4$. The corresponding *gold-salt*, $C^3H^3NBrCl.AuCl_3$, crystallises in golden-yellow needles. (Hofmann, Compt. rend. xlvii. 558.)

6. Trimethyl-vinyl-ammonium. $C^3H^3N = (CH^3)^3(C^2H^2)N$.—The bromide, $C^3H^3NBr^2$, treated with oxide of silver gives up the whole of its bromine and yields a strongly alkaline liquid containing hydrate of trimethyl-vinyl-ammonium, $C^3H^3NO = C^3H^3N \begin{matrix} \text{H} \\ \text{O} \end{matrix}$, which, when neutralised with hydrochloric acid and strongly concentrated, yields with platonic chloride octahedral crystals of the *platinum-salt*, $2C^3H^3NCl.PtCl_4$, and with auric chloride the *gold-salt*, $C^3H^3NCl.AuCl_3$.

The bromide of this base is also formed, together with the preceding, by the action of trimethylamine on bromide of ethylene, part of the latter splitting up into hydrobromic acid and bromide of vinyl: $C^2H^2Br^2 = HBr + C^2H^2Br$. (Hofmann, *loc. cit.*)

7. Trimethyl-amyl-ammonium. $(CH^3)^3(C^5H^5)N$.—The only known salt of this base is the *tri-iodide*, which is obtained by heating a mixture of tri-methylamine and amyl iodide for some time to 160° , and treating the product with tincture of iodine. It crystallises in dark brown flattened rhombic prisms, exhibiting the combination: $\infty P : \infty P_\infty$ (often predominant), $\infty P_\infty : P_\infty$, $\frac{1}{2}P_\infty$. Angle $\alpha P : P_\infty = 104^\circ 28'$; $P_\infty : P_\infty$ at the principal axis = $112^\circ 4'$. The crystals exhibit trichroism; if they are placed upright and viewed so that the light may be transmitted at right angles to ∞P_∞ , the ordinary ray is dark brown or nearly black, the extraordinary ray light red-brown, the third tint being between the two. They melt at 80° , dissolve easily in alcohol, but are nearly insoluble in water. (R. Müller, *loc. cit.*)

This salt and the peroxides of the other bases above mentioned form with mercury, compounds analogous to those already described as produced by the action of mercury on the periodides of tetramethylammonium. (Müller.)

7. Methyl-ethyl-amylamine. $C^5H^5N = (CH^3)(C^2H^2)(C^5H^5)N$.—This base is obtained by the dry distillation of hydrate of methylodiethyl-amyl-ammonium, water and ethylene gas being given off at the same time:

It is a transparent oil, having a fragrant taste and smell, sparingly soluble in water. After drying over potash and rectification, it boils constantly at 135° . It dissolves slowly in acids. The *platinum-salt*, $2C^5H^5NCl.PtCl_4$, which is very soluble in water, is precipitated on mixing its component salts in strong solution, or on evaporating the mixture, in orange-yellow oily globules which gradually solidify in splendid needles. (Hofmann, Chem. Soc. Qu. J. iv. 317.)

8. Methyl-diethyl-amyl-ammonium. $C^5H^5N = (CH^3)(C^2H^2)^2(C^5H^5)N$.—Obtained as an iodide by gradually adding methylic iodide to diethylamylamine contained in a tubulated retort provided with a condenser, the mixture solidifying on cooling into a hard white crystalline mass. This salt is very soluble in water, forming a very bitter solution, from which it is precipitated by potash in oily globules which solidify but slowly.—By digestion with oxide of silver, it is converted into the hydrate, $C^5H^5N.H_2O$, in the form of a strongly alkaline solution which when evaporated to dryness and distilled is resolved into water, ethylene-gas, and methyl-ethyl-amylamine. The sulphate, nitrate, chloride, and chloroplatinate are crystalline. (Hofmann, Chem. Soc. Qu. J. iv. 316.)

METHYL-AMYL ANILINE. See PHENYLAMINES.

METHYL-AMYLIC ETHER. Oxide of Methyl and Amyl, $CH^3.C^5H^5.O$. See AMYL (i. 205).

METHYL-ANILINE. See PHENYLAMINES.

METHYL-ARSINES. See ARSENIC-RADICLES, ORGANIC (i. 400).

METHYLATE OF AMYL. Syn. with METHYL-AMYLIC ETHER.

METHYLATE OF ETHYL. See ETHYLATE OF METHYL, under ETHYL, OXIDE (ii. 542).

* Respecting the constitution of this and similar bases, see AMMONIUM-BASES (i. 196).

METHYLATE OF ETHYLENE. $C^4H^{10}O^2 = \left\{ \begin{smallmatrix} (C^2H^4)'' \\ (CH^3)' \end{smallmatrix} \right\} O^2$.—Wurtz (Ann.

Ch. Pharm. cviii. 84), by distilling a mixture of methylic and ethylic alcohol with sulphuric acid and peroxide of manganese, obtained this compound mixed with methyl-

ethylate of ethylene, $\left\{ \begin{smallmatrix} (C^2H^4)'' \\ C^2H^3 \end{smallmatrix} \right\} O^2$. A compound having the same composition ($C^4H^{10}O^2$)

has recently been obtained by Dancer (Chem. Soc. J. xvii. 222) from crude wood-spirit, and called by him dimethyl-acetal; but it is by no means certain that either this or Wurtz's compound is really a derivative of acetal (see ACETAL, i. 4). Dancer prepared his compound as follows:—Crude wood-spirit, well dried over lime, was distilled upwards for some time with a concentrated solution of caustic soda to decompose the methylic acetate present; the distillate was repeatedly treated with chloride of calcium, as long as that compound continued to take up methylic alcohol from it, then with a concentrated solution of acid sulphite of sodium, to remove the acetone, and afterwards distilled upwards, with caustic potash, to insure the complete decomposition of the remaining methylic acetate, the methylic alcohol formed by the decomposition of this ether being removed by chloride of calcium, and the remaining liquid finally purified by a few distillations on sodium. The product thus obtained had very nearly the composition of dimethylate of ethylene (53.3 per cent. carbon and 11.1 hydrogen), boiled at 63° — 64° ; had a specific gravity of 0.8787 at 6° C. (compared with water at 4° C.) and vapour-density, by experiment 3.165, calc. 3.114.

The liquid called *lignone* by Weidmann and Schweizer, and *xylite* by Völckel, was probably a mixture of this compound with some of the other constituents of crude wood-spirit.

METHYLATE OF POTASSIUM, CH^3KO , and **METHYLATE OF SODIUM**, CH^3NaO .—Compounds similar in properties and reactions to the ethylates of the same metals (ii. 542, 543); they are obtained by the action of potassium and sodium on methylic alcohol.

METHYL-BENZOLIC or **BENZYLENIC ETHER**. See BENZYLENIC ETHERS (i. 577).

METHYL-BROMOSALICYLIC ACID. See SALICYLIC ETHERS.

METHYL-BRUCINE. $C^{24}H^{28}N^2O^4 = C^{23}H^{25}(CH^3)N^2O^4$. (Stahlschmidt, Pogg. Ann. cviii. 503; Jahresb. 1859, p. 398.)—Obtained as a hydriodate, by treating brucine with iodide of methyl. The *hydriodate* crystallises from boiling water in shining laminae containing $C^{24}H^{28}N^2O^4.HI.8H^2O$, and not further altered by treatment with iodide of methyl. By decomposing this salt with oxide of silver (or the sulphate with baryta-water) a solution of methyl-brucine is obtained, which is colourless at first, but soon decomposes, turning violet, and dark red when evaporated, giving off carbonic anhydride, and leaving a solution containing a base different from methyl-brucine. The *hydrobromate*, $C^{24}H^{28}N^2O^4.HBr.5H^2O$, is obtained by mixing the solution of the hydrochlorate with bromide of potassium, as a crystalline precipitate, easily soluble in water and alcohol, and crystallising from the latter in small shining prisms, which give off their water at 130° . The *hydrochlorate*, $C^{24}H^{28}N^2O^4.HCl.5H^2O$, obtained by neutralising the base with the acid, forms small shining crystals easily soluble in water and in alcohol. The *platinum-salt*, $2(C^{24}H^{28}N^2O^4.HCl).PtCl_4$, is a yellow precipitate insoluble in ether, easily soluble in alcohol and in water, and crystallising in needles from the latter. The *gold-salt*, $C^{24}H^{28}N^2O^4.HCl.AuCl_3$, is an orange-yellow precipitate, sparingly soluble in cold water. *Mercuric chloride* added to the solution of the hydrochlorate, forms a white curdy precipitate. The *neutral sulphate*, $(C^{24}H^{28}N^2O^4)^2.H^2SO_4.8H^2O$, obtained by decomposing the hydriodate with sulphate of silver, forms a radio-crystalline mass, easily soluble in water and in alcohol. An *acid sulphate*, $C^{24}H^{28}N^2O^4.H^2SO_4.2H^2O$, obtained by treating the neutral salt with dilute sulphuric acid, forms indistinct crystals somewhat less soluble in water and alcohol.

Methyl-brucine does not appear to be poisonous; 10 grains of the sulphate given to a rabbit did not produce any poisonous effects.

METHYL-BUTYRAL. $C^4H^8O.CH^3$.—A compound produced, together with butyral $C^4H^8O.H$ (i. 689), ethyl-butyral $C^4H^8O.C^2H^5$, and butyrene (i. 697), by the dry distillation of butyrate of calcium. It boils at about 111° , has a specific gravity = 0.827 at 0° , and vapour-density = 3.13.—*Ethyl-butyral* boils at about 128° , has a specific gravity = 0.833 at 0° , and vapour-density = 3.58. (Friedel, Ann. Ch. Pharm. cviii. 122; Jahresb. 1858, p. 295.)

METHYL-CAMPHORIC ACID. See CAMPHORIC ACID (i. 732).

METHYL-CAMPERENE, $C^8H^{14}(CH^3)O$.—A product obtained by the action of sodium and iodide of methyl on camphrene (i. 733). A mixture of equal parts of

camphrene and benzene is treated with sodium in an atmosphere of hydrogen, till the sodium remains unaltered even on heating, and the solution is then cohobated with excess of methylic iodide. On adding water to the resulting liquid, a brown oil is thrown down, which, after repeated rectification, yields methyl-camphrene as a colourless aromatic liquid boiling between 225° and 230° . (H. Schwanert, Ann. Ch. Pharm. cxliii. 298.)

Camphrene is an oily body produced by heating common camphor with sulphuric acid. Chantard, who discovered it, assigned to it the formula $C^{10}H^{10}O$; but according to Schwanert, it has the composition $C^{10}H^{10}O$, isomeric with phorone (q. v.).

METHYL-CAPRINOL. $\left. \begin{matrix} C^{10}H^{18}O \\ CH^3 \end{matrix} \right\}$.—This, according to Harbordt (Ann. Ch.

Pharm. cxliii. 293), is the rational constitution of the essential constituent of oil of rue, regarded by C. G. Williams as euodic aldehyde, $C^{10}H^{18}O.H$. (See RUE, Oil of.)

METHYL-CAPROYL. See METHYL-HEXYL.

METHYL-CARBAMIC ACID. See CARBAMIC ACID (i. 751); also METHYL-AMINE (iii. 99).

METHYL-CARBAMIDES. See CARBAMIDE (i. 754).

According to later experiments by Wurtz (Rép. Chim. pure, 1862, p. 199), dimethyl-carbamide, $\left. \begin{matrix} (CH^3)^2 \\ (CO)^2 \end{matrix} \right\} N^2$, prepared by the action of methylamine on cyanate of methyl, melts at 102.5° and boils between 268° and 270° ; the (identical) compound obtained by treating cyanate of methyl with water, melts at 99.5° , and boils between 273° and 288° .

Methyl-ethyl-carbamide, $\left. \begin{matrix} CH^3.C^2H^5 \\ (CO)^2 \end{matrix} \right\} N^2$, melts at 52° or 53° , and boils between 266° and 268° .

METHYL-CARBONATES. See CARBONIC ETHERS (i. 801).

METHYL-CHLORACETOL. $C^2H^3Cl^2$.—A compound isomeric with chloride of tritylene, produced by the action of pentachloride of phosphorus on acetone (i. 27).

METHYL-CITRIC ACIDS. See CITRIC ETHERS (i. 1001).

METHYL-CHLOROSALICYLIC ACID. See SALICYLIC ETHERS.

METHYL-CONINE. See CONINE (ii. 6).

METHYL-CYANAMIDE. CH^3N^2 = $(H.C^2H^3.Cy)N$. Produced, together with hydrochloride of methylamine, by the action of gaseous chloride of cyanogen on methylamine (Clœtz and Cannizzaro, Ann. Ch. Pharm. lxxviii. 228):

METHYL-CYANANILINE. See PHENYLAMINES.

METHYL-DISULPHOPHOSPHORIC ACID. See PHOSPHORIC ETHERS.

METHYL-DITHIONIC ACID. $CHSO^2$. (J. T. Hobson, Chem. Soc. Qu. J. x. 243.)—An acid produced by the action of sulphurous anhydride on zinc-methyl. The dry gas passed into an ethereal solution of zinc-methyl, kept cool to moderate the action, is rapidly and completely absorbed, and in a little while, a white crystalline substance is formed, which is the zinc-salt of methyl-dithionous acid, $C^2H^3ZnS^2O^4$. This salt may be freed from ether and the last traces of sulphurous acid by evaporation in vacuo. It may be converted into a barium salt by treating it with excess of caustic baryta, and from this the acid may be prepared by precipitating the baryta with dilute sulphuric acid.

Methyl-dithionous acid is a liquid having a feebly acid taste and reddening blue litmus. It decomposes in a short time, with deposition of sulphur, even in a very dilute solution.

The *Methyl-dithionates* cannot be conveniently prepared by digesting the free acid with oxides or carbonates, on account of the facility with which the acid decomposes; but they may be obtained by decomposing the zinc-salt with the corresponding bases, or the barium-salt with the sulphates. Their general formula is CH^3MSO^2 for those containing monatomic metals, and $C^2H^3M^2S^2O^4$ for those containing diatomic metals.

The methyl-dithionates are all very soluble in water, but insoluble in alcohol and ether. The *barium-salt*, $C^2H^3BaS^2O^4$, is prepared by treating the solution of the zinc-

salt with excess of caustic baryta, filtering to separate oxide of zinc, precipitating the excess of baryta by a stream of carbonic acid, and evaporating the filtrate at the heat of the water-bath. It is a colourless, inodorous, crystalline salt, which is precipitated from its strong aqueous solution by alcohol in the form of a white granular powder. A concentrated aqueous solution left to evaporate in vacuo, deposits the salt in cubes arranged in octahedral masses. It sustains a heat of 170° without decomposition.

The *calcium-salt*, $C^2H^4Ca''S^2O^4$, prepared in a similar manner, remains as a solid uncrystallisable mass when its concentrated solution is left to evaporate in a vacuum. The *copper-salt* is obtained as a grass-green solution, which is decomposed by evaporation, with deposition of sulphur. The *magnesium-salt*, $C^2H^4Mg''S^2O^4.H^2O$, obtained by decomposing the barium-salt with sulphate of magnesium or the zinc-salt with magnesia, forms minute colourless crystals. The *nickel-salt* is obtained by double decomposition as a grass-green solution which dries up in a vacuum, with partial decomposition, to a dirty buff-coloured amorphous mass. The *silver-salt* is obtained by dissolving carbonate of silver in the free acid, but the solution decomposes and blackens when exposed to light or heated to 100° . The *zinc salt*, $C^2H^4Zn''S^2O^4$, prepared as above described, separates by evaporation from a very concentrated aqueous solution in small crystals soluble at 100° , but blackening and decomposing with an offensive odour at a somewhat higher temperature.

Methyldithionate of Ethyl.—A mixture of the barium-salt with ethyl-sulphate of potassium distilled at a high temperature, yields an oily liquid together with large quantities of sulphurous anhydride. The product washed with water, dried over chloride of calcium, and redistilled in a vacuum, forms a light straw-coloured liquid slightly heavier than water and having a peculiar fishy odour. It decomposes at the high temperature required to prepare it.

Ethyltrithionic acid, $C^2H^4S^3O^6$, is prepared in a similar manner to methyldithionic acid, the zinc-salt being obtained by the action of sulphurous anhydride on zinc-ethyl. Its salts, which have the general formula $C^2H^4M''S^3O^6$, or for diatomic metals $C^2H^4M''S^3O^6$, are for the most part more stable and more easily crystallisable than the methyl-dithionates. The *barium-salt* dried over oil of vitriol contains $C^2H^4Ba''S^3O^6.H^2O$, gives off its water at 100° , and bears a heat of 170° without decomposition.

The *copper-salt*, $C^2H^4Cu''S^3O^6$ (at 100°), crystallises from aqueous or alcoholic solution in greenish-blue deliquescent needles. The *silver-salt* dried over oil of vitriol in vacuo, contains $C^2H^4Ag''S^3O^6$. It is white, crystalline, very soluble in water, and highly deliquescent. It is not decomposed by light or by heating to 100° , but completely at a somewhat higher temperature. The *sodium-salt*, $C^2H^4Na^2S^3O^6.H^2O$, obtained by dissolving carbonate of sodium in the aqueous acid, separates from the alcoholic solution by evaporation in a vacuum in small ill-defined crystals.

Zinc-salts.—The salt obtained by the action of sulphurous anhydride on zinc-ethyl, is a basic salt containing $Zn^2O.2C^2H^4Zn''S^3O^6.3H^2O$, the excess of zinc-oxide arising from the action of water on the undecomposed zinc-ethyl. By crystallising this salt first from alcohol, then from water, the normal zinc-salt $C^2H^4Zn''S^3O^6.H^2O$, is obtained in minute, colourless, needle-shaped crystals having a peculiar odour, and somewhat bitter taste. It retains its water of crystallisation at 100° , dissolves sparingly in water either hot or cold, also in ether; is nearly insoluble in cold, but moderately soluble in boiling alcohol.

Ethyl-trithionate of ethyl, $C^2H^4(C^2H^5)^2S^3O^6$, prepared by distilling the crystallised barium-salt with ethyl-sulphate of potassium in an oil-bath, is a yellow oily liquid heavier than water, having an offensive odour, insoluble in water, but miscible in all proportions with alcohol. (Hobson, Chem. Soc. Qn. J. x. 55.)

METHYLENE. CH^2 .—This compound, the first of the series of hydrocarbons, C^2H^2 , ethylene being the second, is not known with certainty in the free state. Dumas and Peligot in 1835 (Ann. Ch. Phys. lviii. 28), by passing chloride of methyl through a porcelain tube kept at a cherry-red heat, obtained a gas which they regarded as methylene. After being agitated with water till quite free from hydrochloric acid gas and undecomposed chloride of methyl, and no longer yielded hydrochloric acid when burnt, it appeared as a colourless gas, having no reaction upon vegetable colours. It burnt with a yellow flame, and 2 vol. of it exploded with excess of oxygen, consumed 3 vol. oxygen, and produced 2 vol. carbonic anhydride. Now supposing two volumes of the gas to contain CH^2 , that is to say 2 vol. hydrogen, this quantity of hydrogen would consume 1 vol. O, and the remaining 2 vol. O would form 2 vol. CO^2 with the 1 at. C in the 2 vol. of the gas. The gas could not however have been quite pure, as charcoal was deposited in the tube during its formation. Perrot obtained no evidence of the formation of methylene in the decomposition of methylic chloride by heat. (See p. 987.)

Regnault doubts the existence of methylene, inasmuch as it is not obtained by treating methyl-ether, or wood-spirit, with excess of sulphuric acid. Again, Hofmann finds that it is not produced by the decomposition of hydrate of tetramethylammonium by heat, though the hydrate of tetrethylammonium, when treated in like manner, yields abundance of ethylene.

Methylene is a diatomic radicle forming ethers analogous to those of ethylene. The acetate, bromide, chloride, iodide, oxide, sulphide, and sulpho-carbonate, have been obtained, but the series is at present much less complete than that of the ethylenic ethers.

METHYLENE, ACETATE OF. $C^2H^2O^4 = \frac{(CH^2)^2}{(C^2H^2O)^2} O^4$. (Butlerow, Ann. Ch. Pharm. cxi. 242.)—This compound is produced by the action of iodide of methylene on acetate of silver:

An intimate mixture of the two substances in equivalent quantities, with the addition of crystallisable acetic acid, is heated to 100° for some hours; the resulting mass is distilled in an oil-bath; the distillate is rectified, the portion which distils above 150° being collected apart; this portion is saturated with lime; and the acetate of calcium is dissolved out by water. Acetate of methylene then separates as an oil, which is dried by chloride of calcium, and freed from the last traces of iodide of methylene and acetic acid, by distillation over dry acetate of silver and a small quantity of quicklime.

It is an oily liquid heavier than water, and having an aromatic taste with pungent after-taste. It dissolves in water to a certain extent without decomposition; but when inclosed in a sealed tube with a quantity of water not sufficient to dissolve it at ordinary temperatures, and heated to 100° for twenty hours, it is dissolved and completely decomposed, yielding acetic acid and a solid volatile substance which dissolves readily in water and remains as a white residue when the solution is evaporated in vacuo. Acetate of methylene boiled with aqueous alkalis (potash or baryta-water) or heated with them in sealed tubes, is decomposed, yielding an alkaline acetate, and perhaps also a small quantity of formate. Neither in this decomposition nor in that by water is any hydrate of methylene (methyl-glycol) formed.—When acetate of methylene is heated with water and oxide of lead in a sealed glass tube, acetate of lead is formed, together with oxide of methylene:

It is also decomposed by ammonia, but neither in this case is any methylene-glycol formed. These facts seem to show that methylene-glycol has no existence. (Butlerow.)

METHYLENE, BROMIDE OF. CH^2Br^2 .—Produced by the action of bromine on the iodide. (Butlerow.)

METHYLENE, CHLORIDE OF. CH^2Cl^2 .—Produced by the action of chlorine on iodide of methylene (Butlerow, Ann. Ch. Pharm. cvii. 110; cxi. 242). When chlorine gas is passed into iodide of methylene covered with water in a retort, and the retort is gently heated, a very volatile liquid passes over into the receiver, and iodine separates in the crystalline form. The oily liquid, which is chloride of methylene, is purified by heating it with chlorine and a few drops of potash-lye, drying over chloride of calcium, and rectifying.

It is a colourless liquid, heavier than water, but lighter than the iodide. It has a penetrating odour very much like that of chloroform. Does not solidify in a mixture of snow and salt. Boils at about 40°.

According to the known boiling points of the chlorides of tetraylene, tritylene, and ethylene, that of chloride of methylene should be 65° instead of 40°. Now according to Wurtz, the difference of boiling point between chloride of ethylene and the isomeric body chloride of ethylidene (ii. 599) is 25°. If then this same difference between the boiling points of chloride of methylene and chloride of methylidene, is also 25°, the latter should boil at 40°, as the compound now under consideration actually does. Hence Butlerow thinks it not improbable that this compound is really *chloride of methylidene*, and consequently that the iodide of methylene above described is also really an iodide of methylidene; but till this point is satisfactorily ascertained, it is best to designate these bodies as methylene-compounds.

Chloride of methylene, or its isomer, monochlorinated methylic chloride, $CH^3Cl.OCl$,

is produced, together with chloroform (CHCl_3), by bringing chloride of methyl and chlorine together in sunshine, and condensing the products by refrigeration (p. 988). (Regnault, Ann. Ch. Phys. [2] lxx: 377). The compound thus obtained has, however, a much lower boiling point, viz. 30.5° (Regnault). It unites with triethyl-phosphine, forming a crystalline mass of chloride of chloromethyl-triethyl-phosphonium: $\text{CH}_2\text{Cl}_2 + (\text{C}^2\text{H}_5)_3\text{P} = (\text{CH}_2\text{Cl})(\text{C}^2\text{H}_5)_3\text{P} \cdot \text{Cl}$. (Hofmann.)

Chloride of Dinitromethylene. $\text{C}(\text{NO}_2)_2\text{Cl}_2$. (Marignac, Rev. scient. v. 375.)—This compound, which is closely related to chloropierin, $\text{C}(\text{NO}_2)_2\text{Cl}_2$ (i. 922), and is commonly known by the name of *Marignac's oil*, is obtained by condensing the gaseous products of the action of chlorine on naphthalene, and purifying the product, which separates after a while from the acid liquid in the receiver, by distillation with water. It is a colourless, transparent liquid, having a specific gravity of 1.685 at 15° , a pungent odour like that of chloride of cyanogen, and producing great irritation of the eyes. It is neutral to vegetable colours. Water dissolves only traces of it, but sufficient to impart the odour. It is very soluble in alcohol and ether, very slightly soluble in hydrochloric acid. Its boiling point is above 100° ; but it distils with vapour of water. Metallic mercury absorbs the vapour, producing a mixture of chlorine, carbonic anhydride, and nitric oxide. It is not acted on by aqueous potash, but alcoholic potash dissolves it easily, the odour disappearing after some time, and a crystalline salt being precipitated which is decomposed with deflagration when heated.

METHYLENE, IODIDE OF. CH_2I_2 . (Butlerow, Ann. Ch. Pharm. cvii. 110; cxl. 242.)—This compound is produced by the action of iodoform on ethylate of sodium; probably together with oxide of ethylene, thus:

The best result is obtained when 9 at. ethylate of sodium (in not too concentrated solution), and not turned brown by exposure to the air, are gradually added to 4 at. pulverised iodoform. On adding water to the product, iodide of methylene separates as an oily liquid which must be washed with water and rectified over chloride of calcium. It is a yellowish strongly refracting liquid, of specific gravity 3.342 at $+5^\circ$; at $+2^\circ$ it solidifies to a mass of broad shining crystalline laminae.

Butlerow regards it as probable that the substance which Serullas obtained (Ann. Ch. Phys. xxv. 311), by the action of pentachloride of phosphorus on iodoform, was iodide of methylene; also the compound which Brüning produced (Ann. Ch. Pharm. civ. 187), by treating iodoform with alcoholic potash:

Iodide of methylene is not decomposed by potassium at ordinary temperatures, but on applying heat, an evolution of gas immediately takes place, ending with a violent explosion. Sodium acts in a similar manner, but the explosion is less violent. When sodium-amalgam containing $\frac{1}{4}$ of sodium is rubbed to powder and heated with iodide of methylene, a combustible gas is evolved, and iodide of sodium is formed, together with a blackish carbonaceous substance which glimmers away when set on fire. The gas is chiefly hydrogen, but appears to contain a small quantity of methylene; for when it is passed into bromine, after having been freed from vapours of iodide of methylene and of alcohol by passing first through alcohol and then through water, and the bromine is afterwards treated with potash, a small quantity of oil is left undissolved having an odour like that of Dutch liquid. Heated with metallic copper and water in sealed tubes, it yields cuprous iodide and a gaseous mixture containing carbonic anhydride, carbonic oxide, and marsh-gas, together with ethylene and some of its higher homologues, but no methylene (Butlerow, Ann. Ch. Pharm. cxx. 356). Iodide of methylene treated with acetate of silver is converted into acetate of methylene (Butlerow). With triethylphosphine it reacts similarly to the chloride. (Hofmann.)

METHYLENE, OXIDE OF. *Dioxymethylene*, $\text{C}^2\text{H}_2\text{O}_2 = \begin{Bmatrix} \text{CH}_2 \\ \text{CH}_2 \end{Bmatrix} \text{O}_2$. (Butlerow, Ann. Ch. Pharm. cxl. 242; cxx. 293.)—This compound, isomeric with acetic acid and methyle formate, is produced—1. By the action of oxalate of silver on iodide of methylene:

2. By the action of oxide of silver on iodide of methylene.—3. By that of lead-oxide on acetate of methylene.—4. By the dry distillation of ethyl-glycollic acid (ii. 916). (Heintz, Jahresb. 1861, p. 448.)

Preparation.—When 1 at. iodide of methylene is intimately mixed with 1 at. oxalate of silver, and heated, a violent explosive action takes place; but if the mixture be previously triturated with twice its weight of pounded glass—or better, if it be heated under a layer of rock-oil—a slow and regular decomposition takes place; gas is abun-

dantly evolved, consisting of carbonic anhydride and carbonic oxide; and dioxymethylene sublimes in the neck of the retort, or passes over with the vapour of rock-oil into the receiver, and there condenses in a thin white layer, which adheres closely to the sides of the receiver. It is purified by pressure between paper, and washing with ether, alcohol, and water, then with alcohol and ether, in the order here mentioned, and lastly dried over oil of vitriol and sublimed in sealed tubes.

Properties.—Dioxymethylene forms translucent, hard, crystalline crusts having an indistinct crystalline structure. It is odourless at ordinary temperatures, but emits a peculiar, sharp, irritating odour when heated. Tasteless. Neutral to litmus paper. May be sublimed without previous fusion. Begins to volatilise at 100° , but is not completely vaporised till heated above 150° ; at about 152° it melts, and immediately afterwards begins to boil. A lump of it quickly heated, melts and boils at the same time. Vapour-density, obs. = 2.07; calc. = 2.08. It does not dissolve in water, alcohol, or ether when merely boiled with them; but when heated with water to 100° , in a sealed tube for several hours, it dissolves completely, forming a solution which when evaporated in a vacuum, leaves a residue consisting chiefly of the unaltered oxide. This compound does not therefore behave with water like oxide of ethylene, C^2H^4O , and indeed cannot be regarded as the ether of the hypothetical methylene-glycol, inasmuch as that ether should have the composition CH^2O , but it appears rather to be the homologue of dioxethylene, $(C^2H^4)^2O^2$ (ii. 599).

Decompositions.—1. Dioxymethylene has a great inclination to take up an additional quantity of oxygen, being thereby converted into carbonic anhydride and water, and sometimes partially into formic and oxalic acid. It reduces the oxides of silver and mercury when heated with them. Nitric acid and a mixture of sulphuric acid and chromate of potassium converts it into carbonic anhydride and water. Inclosed together with spongy platinum in a sealed tube containing oxygen, it oxidises slowly at ordinary, quickly at higher temperatures, yielding carbonic acid and water. Heated to 100° for about 10 hours in sealed tubes with water and peroxide of lead, it yields carbonate and formate of lead. In the preparation of this compound by the process above given, part of it appears to be oxidised by oxygen derived from the oxalate of silver: for the volume of carbonic evolved is greater than that of the carbonic oxide (they should be equal according to the above equation); and towards the end of the operation, oxalic acid sublimes in crystals: $C^2H^4O^2 + O^2 \rightarrow C^2H^4O^4 + H^2O$. — 2. With red iodide of phosphorus it yields iodide of methylene, and is at the same time partially carbonised. — 3. When ammonia-gas is passed over pulverised oxide of methylene, heat is evolved, a watery liquid is separated, and a volatile crystalline substance is formed possessing basic properties. — 4. It is decomposed by heating with *blue-water* or dilute *potash-lye*, into formate and methylenitan (p. 1008).

METHYLENE, SULPHIDES OF. (A. Husemann, Ann. Ch. Pharm. cxxvi. 293.)—*Monomethylene sulphide*, CH^2S , is obtained by heating monosulphide of sodium with iodide of methylene, as a loose white insoluble powder. When heated to 150° it is converted into a sublimable body, consisting of *dimethylene sulphide*, $(CH^2)^2S^2$, and probably identical with the compound which Girard (Ann. Ch. Pharm. c. 306) obtained by the action of nascent hydrogen (from zinc and hydrochloric acid) on sulphide of carbon. When obtained as above, it crystallises in long monoclinic prisms having an intolerable odour of onions, melting at a temperature above 200° , but volatilising in considerable quantity at a much lower temperature. It is sparingly soluble in most liquids, most readily in benzene and sulphide of carbon. It forms crystalline double salts with the chlorides of mercury, gold, and platinum, also with nitrate of silver, and unites directly with iodine, forming a crystalline compound, but not with bromine. Fuming nitric acid attacks it violently, giving off nitrous fumes and forming a compound which crystallises in acute rhombohedrons, and probably consists of dimethylene oxysulphide, $\begin{matrix} CH^2 \\ CH^2 \end{matrix} \{ S^2O^2$ (Husemann).

Girard's compound resembles that just described in its behaviour with solvents (from benzene it crystallises in quadratle prisms), and in forming crystalline compounds with nitrate of silver and the chlorides of gold and platinum; it was dissolved without decomposition by hydrochloric acid, slightly also by dilute sulphuric acid; when heated with strong sulphuric acid it decomposed, with separation of sulphur. Hot nitric acid decomposed it completely, with formation of sulphuric acid, carbonic acid, and water.

METHYLENE, SULPHOCARBONATE OF. $\begin{matrix} CS^2 \\ CH^2 \end{matrix}$ $\{ S^2$.—Separates gently heating an alcoholic solution of dioxymethylene with sulphocarbonate of sodium, as a yellowish-white, amorphous, inodorous powder, insoluble in water, and converted by

fuming nitric acid into methylene-sulphurous acid (Hofmann and Buckton's disulphometholic acid; Liebig's methionie acid). (Husemann.)

METHYLENE-PHOSPHONIUMS. See PHOSPHORUS-RADICLES, ORGANIC.

METHYLENE-SULPHUROUS ACID. See SULPHUROUS ETHERS.

METHYLENITAN. $C^4H^{10}O^4$. (Butlerow, Ann. Ch. Pharm. cxx. 295.)—A saccharine substance somewhat resembling mannite, produced, together with formic acid, by the action of strong bases on dioxymethylene:

Dioxymethylene dissolves when boiled with excess of baryta- or lime-water, and if lime-water be gradually added to the boiling solution till it assumes a deep yellow colour, the liquid remains neutral, is no longer precipitable by carbonic acid, and when evaporated in a vacuum, yields a yellowish syrup, consisting of methylenitan, mixed with crystalline calcic formate. On treating this residue with absolute alcohol, the methylenitan dissolves, and remains, on evaporating the alcohol, as an amorphous body (containing a little lime) having a saccharine taste, and a faint odour like that of caramel. The solution has a slight acid reaction, is coloured yellow by alkalis, and decolorised again by acids; it reduces an alkaline cupric solution almost instantly when heated with it; has no rotatory power; and does not appear to ferment with yeast. When heated for several hours to 100° , with excess of butyric acid, it forms an oily bitter compound, probably $C^4H^{11}(C^4H^7O)^2O^6$, having an odour of cheese, insoluble in water, partially volatilised in a current of air at 150° , and yielding butyrate of barium when saponified by baryta-water.

METHYL-HEPTYLIC ETHER. Syn. with HEPTYL-METHYLIC ETHER.

METHYL-HEXYL, or *Methyl-caproyl*. $C^7H^{16} = CH^3.C^6H^{13}$.—Obtained by the electrolysis of a mixture of acetate and cænanthylate of potassium, but in small quantity only, probably because cænanthylic acid is much more easily electrolysed than acetic acid. On rectifying the resulting oily liquid, the portion which distils at 85° is found to consist chiefly of methyl-hexyl, having a vapour-density of 3.426 (calc. 3.466). (Wurtz, Ann. Ch. Phys. [3] xlv. 275.)

METHYLIA. Syn. with METHYLAMINE.

METHYLIDENE-COMPOUNDS. See p. 1006.

METHYL-ONANTHYL. $C^8H^{10}O = CH^3.C^8H^9O$. (Städeler, J. pr. Chem. lxxii. 246.)—A compound acetone, isomeric with caprylic aldehyde, obtained by distilling a mixture of equivalent quantities of acetate and onanthylate of sodium; also, together with heptylic or octylic alcohol, by distilling ricinoleate of potassium or sodium with excess of caustic alkali (see HEPTYL, HYDRATE OF, p. 144). It is a thin, colourless, neutral liquid of specific gravity 0.817 at 23°; boiling between 171° and 171.5°. Its smell recalls that of oil of rue; taste similar, and slightly burning. It makes grease-spots on paper; does not turn acid on exposure to the air, even in contact with platinum-black; burns with a bright yellow flame. It is insoluble in water, but mixes in all proportions with alcohol and ether; mixes with sulphuric acid, evolving heat, and is precipitated from the yellow solution by water, apparently unchanged. With ammonia, potash, silver-oxide, and chromic acid, it behaves like caprylic aldehyde (i. 745). With pentachloride of phosphorus, it yields chloride of octylone, $C^8H^{10}Cl^2$. (Dachauer, Ann. Ch. Pharm. cvi. 269.)

METHYLURAMINE. $C^4H^7N^2$. (Dessaignes, Compt. rend. xxxviii. 839.)—A base produced by heating an aqueous solution of creatine or creatinine with mercuric oxide: carbonic anhydride is then evolved without a trace of ammonia; the oxide of mercury is partly reduced; and oxalate of methyluramine is obtained in crystals:

If the quantity of oxide of mercury is too small, the crystals of oxalate of methyluramine are mixed with crystals of creatine; but when a sufficient quantity of mercuric oxide is used, the oxalate of methyluramine is obtained in large quantity and quite free from creatine. To separate it completely, the solution must be repeatedly treated with alcohol and evaporated. It may also be produced by treating creatine with peroxide of lead and sulphuric acid; but this method does not yield so pure a product as the preceding. (Dessaignes, Compt. rend. xli. 1268.)

Methyluramine is obtained in the free state by heating the oxalate with a slight excess of pure milk of lime, and evaporating the filtrate in vacuo. It is a white solid body having a crystalline surface, due perhaps to absorption of carbonic acid; very deliquescent. Its taste is caustic and ammoniacal. Heated on platinum-foil, it volatilises completely, exhaling a strong odour of burnt creatine.

Methyluramine contains the elements of urea and of methylamine, minus 1 at. water (Dessaignes):

It may also be regarded as formed from 2 at. ammonia, by the replacement of 2 at. H

by 1 at. cyanogen and 1 at. methyl respectively: $C^2H^2N^3 = N^2 \begin{Bmatrix} CN \\ CH^2 \\ H^2 \end{Bmatrix}$ (Gerhardt, .

Traité, iii. 941.)

Methyluramine heated with baryta-water is decomposed, giving off ammonia with an odour of sea-water. It eliminates ammonia from ammonical salts at ordinary temperatures. With the chlorides of barium and calcium, it forms copious precipitates, which are soluble in a large quantity of water, and in dilute acetic acid. With sulphate of aluminium and ferric chloride, it forms precipitates which redissolve in an excess of the precipitant. It precipitates the salts of lead, copper, and mercury; forms a whitish-yellow precipitate with nitrate of silver, and dissolves oxide and chloride of silver.

Methyluramine combines with acids, forming crystalline salts, which have a slight alkaline reaction, and when heated with caustic potash-solution, give off copious alkaline vapours consisting of ammonia and methylamine. The *sulphate*, *hydrochlorate*, and *nitrate* may be easily obtained by decomposing the oxalate with the corresponding calcium-salts.

The *chloroplatinate*, $2(C^2H^2N^3.HCl).PtCl_4$, is obtained, by mixing a concentrated solution of the hydrochlorate with platinum chloride, in splendid orange-coloured rhomboids, which, when redissolved and recrystallised by cooling, often take the form of flat prisms, arranged in parallel groups. The salt when calcined emits an odour of trimethylamine.

The *oxalate*, prepared as above, forms flattened prisms arranged in parallel groups, containing $(C^2H^2N^3)^2.C^2H^2O^4.2H^2O$. It gives off its water of crystallisation at 100° , is very soluble in water, has a disagreeable taste, and blues reddened litmus slightly. Heated on platinum-foil, it exhales the same odour as creatine.

METHYL-UREAS. See METHYL-CARRAMIDES, under CARRAMIDES (i. 754).

METHYL-XANTHIC ACID. See XANTHIC ETHERS.

METOLUIDINE. Syn. with MELOBENZYLAMINE. See BENZYLAMINE (i. 576)

METHYSTICIN. A crystalline substance obtained from Kawa-root, the root of *Piper Methysticum* (see KAWA, p. 445).

MEZEREUM-SEEDS. M. Martius (Arch. Pharm. [2] ex. 39) obtained from 3 lbs. of mezereum-seeds (*Semen coccognidii*), between 20 and 26 oz. of a fatty vesicating oil, and about 2 drms. of a substance which crystallised from alcohol in white cauliflower-like masses.

MIARGYRITE. A sulphantimonite of silver, $Ag^2S.Sb^2S^3$ or $AgSbS^3$, found at Bräunsdorf, near Freiberg in Saxony, associated with argentiferous arsenical pyrites. It forms thick tabular, pyramidal, or short prismatic crystals belonging to the monoclinic system. Ratio of axes $a : b : c = 0.3665 : 1 : 1.0377$. Angle of inclined axes = $81^\circ 36'$; $\alpha P = 39^\circ 38'$; $\alpha P : [P\infty] = 109^\circ 9'$. The lateral planes are deeply striated. Cleavage parallel to $\alpha P\infty$ and $[P\infty]$, imperfect. Hardness = 2. Specific gravity = 5.2 to 5.4. The crystals are opaque, with sub-metallic adamantine lustre and iron-black colour; thin splinters appear blood-red by transmitted light. Streak dark cherry-red. Fracture subconchoidal. Very sectile. Contains according to H. Rose (Pogg. Ann. xv. 469), 21.95 per cent. sulphur, 39.14 antimony, 36.40 silver, 1.06 copper, and 0.62 iron (= 99.17); the formula requires 21.2 sulphur, 42.9 antimony and 35.9 silver. In an open tube it melts easily, gives off sulphurous anhydride, and yields a sublimate of antimonious oxide.

The *Hypargyrite* of Breithaupt contains, according to Plattner, 35 per cent. silver, and is probably a variety of miargyrite. (Dana, ii. 75.)

MIASCITE. A granular slaty rock consisting of orthoclase, mica, and clæolite sometimes with quartz, albite, and hornblende.

MICA. The generic name of a number of mineral species, including Muscovite, Phlogopite, and Biotite, distinguished by a more or less laminated structure, hence called *micaceous*. They are usually divided optically into uniaxial and biaxial micas, but in reality they are all biaxial, and apparently trimetric; but in some, viz. the biotites,

the angle between the optic axes is small, not amounting to 5° , while in others, viz. the muscovites, it varies between 45° and 55° .

Chemically, micas may be divided into potash-micas, containing little or no magnesia, these being again subdivided into those which contain lithia, and those which are free from that alkali; and magnesia-micas, containing for the most part from 20 to 30 per cent. of magnesia. The micas which do not contain magnesia are those in which the optic angle of the axes is the largest: hence they are commonly distinguished as biaxial micas.

The micas, even of the same subdivision, present such differences in chemical composition (at least, according to the analyses that have hitherto been made of them), that it is not an easy matter to bring them under general formulæ. According to Rammelsberg, however, they may be represented, with considerable approach to accuracy, as follows, M denoting a mon-atomic, and R a sesqui-atomic metal:

According to these formulæ, the magnesia micas are orthosilicates, both terms of the second formula being reducible to the form $\text{M}^{\cdot}\text{SiO}_4$, whereas, in the formula of the potash-micas, only the second term can be thus reduced, the first containing 2 at. silica in addition.

I. POTASH-MICA.

a. Not containing Lithia.

Muscovite. *Common, Oblique or Biaxial Mica. Muscovy glass, Verre de Muscovie, Glimmer*, in part.—This mineral occurs in trimetric forms, usually hemihedral, and having a monoclinic aspect. $\angle P : \angle P' = 120^\circ$. Cleavage basal-eminent; occasionally also at right angles to two opposite sides of $\angle P$; separating in fibres. It also forms twins, often observable by internal markings or by polarised light; face of composition parallel to $\angle P$. Folia sometimes aggregated in stellar or plumose groups. Hardness = 2 to 2.3. Specific gravity = 2.75 to 3.1. Lustre more or less pearly. Colour white, grey, pale green, and violet-yellow, sometimes brown and dark olive-green; colours different in the axial and diametral directions. Streak uncoloured. Transparent to translucent. Thin laminae, flexible and elastic. Very tough. Sectile. Biaxial; angle between optic axes varying from 45° to 75° .

When heated, it gives off more or less water, which exhibits with glass the reaction of hydrofluoric acid. Melts before the blowpipe more or less easily, to a grey or yellowish tumefied glass. Gives with fluxes the reactions of silica and iron (sometimes of manganese).

Analyses: a. From Litchfield in the State of Maine: white (Smith and Brush).—b. County of Carlow, Ireland: grey; angle of axes = $72^\circ 18'$ (Haughton).—c. Glendalough valley, County of Wicklow: angle of axes = $70^\circ 4'$; specific gravity = 2.793 (Haughton).—d. Ceux, near St. Etienne in the Vosges: greyish-white, reddish by transmitted light; specific gravity = 2.817 (Delesse).—e. Zsidovacz, in Hungary: white; specific gravity = 2.817 (Kussin).—f. Schwarzenstein, Zillertal (chromemica; fuchsite): green (Schafhäutl).—g. Utö, Sweden: golden-yellow (H. Rose).—h. Ochotzk, Siberia (H. Rose).

Common mica is a constituent of granite and its associate rocks, gneiss, syenite and mica-slate. It occurs also in more recent aggregate rocks; also in imbedded crystals in granular limestone, wacke, trachyte and basalt. Coarse lamellar aggregations of it often form the matrix of crystals of topaz, tourmaline, and other mineral species.

Mica is sometimes altered by the action of water, losing its elasticity and transparency, and often some portions of its alkalis and ferric oxide. *Margarodite* (p. 853) appears to be a mica thus altered; also, perhaps, *Damourite* (ii. 303); *Gilbertite*, a mineral found at Stonagwyn, near St. Just in Cornwall, containing, according to Lehunt, 45.15 per cent. silica, 40.11 alumina, 2.43 ferric oxide, 4.17 lime, 1.9 magnesia, and 4.25 water; and *Sericite* (q. v.).

B. Containing Lithia.

Lepidolite. Trimetric, often occurring in oblique, rhombic, and six-sided prisms of 119° to 120° ; also in coarsely granular masses consisting of foliated scales. Cleavage basal, highly eminent. Hardness = 2.5 to 4. Specific gravity = 2.84 to 3. Lustre pearly. Colour rose-red, violet-grey, yellowish, whitish. Translucent. Angle of apparent optic axes = 70° – 78° .

When heated, it gives off water exhibiting a strong reaction of hydrofluoric acid. Heated before the blowpipe, either alone or with a mixture of fluor spar and acid sulphate of potassium, it colours the flame red (in the latter case sometimes also green from the presence of boron, C. Gmelin). Melts easily before the blowpipe, and exhibits the reactions of iron and manganese. It is attacked with difficulty by hydrochloric and sulphuric acid; after fusion, the finely pulverised mineral gelatinises with the acid.

Analyses: a. From Zinnwald in the Erzgebirge (Lohmeyer); b. From the same locality (Rammelsberg); c. Altenberg in the Erzgebirge (Stein); d. Cornwall (Turner); e. Rozena in Moravia (Rammelsberg); f. Utö in Sweden (Turner); g. Chursdorf in Saxony (C. Gmelin); h. Juschakowa in the Ural (Rosales).

The lithia-micas contain a larger proportion of manganese than those in the preceding division. Rammelsberg restricts the name lepidolite to those which are free from iron.

2. MAGNESIA-MICAS.

The micas of this division, mostly of dark green, brown or black colour, contain only about 40 per cent. silica, often a large quantity of iron, and magnesia as an essential constituent, sometimes to the amount of 30 per cent.

Potash is also present, but in comparatively small quantity. Moreover these micas almost always contain fluorine, and frequently water. Before the blowpipe they melt, for the most part with difficulty, to grey or blackish glasses; with fluxes they give a strong iron-reaction. They are attacked with difficulty by hydrochloric, but completely decomposed by sulphuric acid, the silica remaining in the form of the laminae with white colour and mother-of-pearl lustre.

Phlogopite. Rhombic Mica.—Trimetric, occurring in rhombic or hexagonal prisms, with biaxial refraction. $\infty P : \infty P = 120^{\circ}$. Colour yellow or copper-red; also white or colourless and different shades of brown. Cleavage as in muscovite. Angle of apparent optic axes, 5° (or less) to 20° .

Analyses: a, b, c. From Edwards, St. Lawrence County, New York: a. dark yellow-brown; b. and c. colourless, with silvery lustre (Craw).—d. From the Vosges: in granular lime-stone: greenish; specific gravity, 2.746 (Delesse).—e. Jefferson County,

New York: brown; fuses easily before the blowpipe to a white enamel, and colours the flame reddish (Meitzendorf).—*f.* Sala in Sweden (Svanberg).

* With lithia.

This kind of mica is especially characteristic of granular limestone. The phlogopites are very liable to change, losing their elasticity and becoming pearly in lustre, often with brownish spots, as if from the hydration of the oxide of iron. In some cases, an alteration to steatite has been observed.

Biotite. *Hexagonal Mica. Uniaxial Mica.*—Probably trimetric, formerly supposed to be hexagonal. Occurs usually in tabular prisms with basal cleavage, highly eminent; common also in foliated masses. Refraction biaxial; angle between the axes less than 60° . Hardness = 2.5 to 3. Specific gravity = 2.7 to 3.1. Lustre pearly, often submetallic on the terminal faces of the prism. Colours various, as in the preceding species; usually dark green, brown, or nearly black; sometimes white or colourless. Streak uncoloured. Transparent to opaque. Thin laminae, flexible and elastic.

Analyses: *a.* From Lake Baikal in Siberia (H. Rose).—*b.* Vesuvius: yellowish green; crystallised (C. Broméis).—*c.* Monroe, New York: dark green (v. Kobell).—*d.* Greenwood Furnace, near Monroe: dark green (v. Hauer).—*e.* Schwarzenstein in the Zillerthal: green (chrome-mica) (Schafhäütl).—*f.* Eifel: pinchbeck brown (Kjerulf).—*g.* From the protogyne of the Alps: dark green; specific gravity = 3.127. Difficult of fusion before the blowpipe: perfectly decomposable by hydrochloric acid (Delesse).—*h.* Abberfoss in Finland (Svanberg).

This species is perhaps identical with the preceding; indeed no definite line of demarcation can be drawn between them. Since the percentage of iron decreases, for the most part, as the magnesia increases, part of the iron must be present as ferrous oxide. (Rammelsberg.)

Vesuvian biotite occurs in brilliant well-defined crystals; that from Greenwood Furnace, New York, in large very regular rhombic prisms, and tetrahedral pyramids.

Biotite occurs altered to rubellan and steatite; it has also been observed altered to magnetite in the Tyrol.

For further details respecting the optical properties of micas, see Dana's *Mineralogy*, ii. 217, and for a full discussion of the chemical formulæ, Rammelsberg's *Mineralchemie*, pp. 656-672.

MICA-SLATE. A rock similar in constitution to granite, but with a distinctly foliated structure.

MICHAELITE. A white, fibrous, pearly variety of opal, from the island of St. Michael in the Azores.

MICROBROMITE. A variety of bromochloride of silver. (See SILVER.)

MICROCLIN. A variety of orthoclase from Arendal in Norway. Breithaupt, however, regards it as triclinic, although the angle between the principal directions of cleavage differs by only 22' from 90°. According to Breithaupt, also, the felspar of miascite (p. 1009) consists of microclin.

MICROCOSMIC SALT. Ammonio-sodic phosphate, $(\text{NH}_4)\text{NaHPO}_4 \cdot 4\text{H}_2\text{O}$, used as a flux in blowpipe experiments. (See BLOWPIPE, i. 624, and PHOSPHATES.)

MICROLITE. A variety of pyrochlore from the albite vein in Chesterfield, Massachusetts. (See PYROCHLORE.)

MIDDLETONITE. A fossil resin found in the coal-seams at the Middleton collieries near Leeds, and at Newcastle. It is brownish-red, of specific gravity 1.6, nearly insoluble in alcohol, ether, and oil of turpentine, and contains 86.43 per cent. carbon, 8.01 hydrogen, and 5.56 oxygen. (Johnston, *Phil. Mag.* [3] xii. 261.)

MIEMITE. Syn. with DOLOMITE.

MIESITE. Syn. with PYROMORPHITE.

MILK is the liquid secreted by the mammary glands of the class of animals called *Mammalia*. Its colour is generally white, often bluish-white, more rarely yellowish; it is opaque, has little or no smell, a slightly sweet taste, and in general an alkaline reaction. The specific gravity of milk varies between 1.018 and 1.045 (Scherer); the average specific gravity of human milk = 1.032 (Simon); = 1.03267 (1.02561 - 1.04648). (Vernois and Becquerel.)

Chemists differ as to the reaction of fresh milk. Berzelius, Peligot, and Lassaigne ascribe an acid reaction to normal milk; Simon and others, an alkaline reaction, and consider that when it is acid, that quality is due either to the milk having been allowed to stand before testing, or to disease. Moleschott, however, found that in two cases, cow's milk (stall-fed) which had just been drawn was acid. Elsässer examined 385 different specimens of human milk, some diseased, but most healthy; of these 45 were neutral, and the rest alkaline. Rattenmann, out of 272 specimens, found only two acid, and that probably owing to some extraneous cause. On the contrary, out of 94 specimens of fresh cow's milk, Rueff found 44 acid; out of 46 specimens of mare's milk, 19 acid; sheep's milk as often acid as alkaline or neutral; and the milk of carnivorous animals (dogs and cats) always acid. Dumas remarked that dog's milk coagulates by heat like turned cow's milk. Peligot found ass's milk always acid (15 cases). The reaction of the milk seems in some measure to depend upon the nature of the food. According to D'Arat and Petit, the milk of stall-fed animals is always acid, and becomes alkaline only when they are turned out to grass. Hermbstädt found milk that had remained long in the udder, acid. Fraas caused a cow to be milked six times in a day, and found the milk in each case feebly alkaline; after an interval of 24 hours, the cow was again milked, when the first portion of the milk was found to be alkaline, the last acid. Schlossberger, however, found the milk of a cow which had not been milked for 14 days, alkaline. In some experiments the milk was as often acid as alkaline, but that drawn in the morning was more often acid than evening milk.

When milk has stood for some time, a thick yellowish-white stratum, rich in fat, collects on its surface (*cream*); while the lower portion becomes bluish-white, and poorer in fat, and at the same time increases in specific gravity. If the surrounding temperature be not too low, the milk, when previously alkaline, acquires an acid reaction, but remains homogeneous for a time. It then coagulates, fresh milk more quickly than boiled, and more rapidly if the temperature be rather elevated, and the atmosphere charged with electricity. Milk is immediately coagulated by rennet. If it be rapidly evaporated, a dense white film forms on its surface.

The spontaneous coagulation of milk appears to be caused by part of the milk-sugar undergoing acid fermentation, and thus yielding lactic acid, which precipitates the casein. A solution of pure casein is not precipitated in 10 hours by rennet, and milk rendered alkaline by addition of alkali is not coagulated by rennet (Denis). Selmi, however, coagulated alkaline milk in ten minutes with rennet, and the mother-liquor was still alkaline after the precipitation of the casein. (See CASEIN.)

Viewed under the microscope, fresh milk appears as a clear liquid in which the so-called *milk-globules* are suspended. They vary considerably in size (diameter = between 0.0012" and 0.0018"), and rarely in fresh milk attain the diameter of 0.0038". Without the addition of reagents, they appear merely as globules of fat.

Henle first proved the existence of an external envelope; he added acetic acid to the milk, and found that the shapes of the globules were thereby distorted. Mitscherlich found that the globules were not dissolved when milk was shaken up with ether, which would have been the case if they were a simple emulsion of fat; if, however, caustic potash or carbonate of potassium, which dissolves the envelope, was previously added, the fat was then dissolved by ether. Lehmann also remarked that the surface of the globules in milk merely treated with ether, appeared less transparent, turbid, and wrinkled, as if it had been coagulated; the ether took up the fat on the addition of phosphate of sodium. Moleschott acted on the coagulum, obtained by adding alcohol to milk, with acetic acid, and extracted the fat with ether; there remained many unbroken fat envelopes in the form of little vesicles, which he was able to fill with an ethereal solution of chlorophyll; they contained no fat. From this he not only proved the existence of the fat envelopes, but concluded also that they are organised. (*Zeitschr. fr. Physiol. Hilk.* xi. p. 696-708.)

Another kind of morphological elements, the so-called *granular bodies* (*corps granuleux, Colostrumkörperchen*), occurs in the colostrum (the milk secreted during the first two or three days after parturition). They consist of irregular conglomerations of very small fat-vesicles, united by an amorphous and somewhat granular substance. Their diameter = about 0.0111" (Henle), but varies between 0.0063" and 0.0232". Their fat is much more easily dissolved by ether than that of milk-globules. They are destroyed by potash or by acetic acid; iodine-water imparts an intensely yellow colour to them; hence they consist of very small globules of fat imbedded in an albuminous substance. They are found in human milk up to the third or fourth day after child-birth, sometimes, however, as late as 20 days after. Moleschott found in the colostrum of cows, together with milk-globules, five different kinds of granular bodies and globules (*loc. cit.*).

Human colostrum is at first yellow, on the first and second day; it then becomes lighter, and on the third or fourth day becomes white. According to G. Veit, in the passage of colostrum to milk, the milk-globules (which cohere in the colostrum) lose this property, and the largest (above 0.00166" in diameter) disappear, when a richer secretion is formed, and albumin ceases to be present in the milk. The secretion of normal milk begins on the fourth day at the earliest, but generally between the sixth and tenth day.

Epithelium-cells and *mucus-globules* are of only accidental occurrence in milk.

Fibrin occurs only when the milk contains blood.

Sometimes *infusoria* or *plants* low in the scale of organisation are found in blue cow's milk, and in that of women (Vogel). T. Fuchs ascribes the blue colour of milk to an infusorium which he calls *Vibrio cyanogenus*; Baillieu ascribes it to a *Byssus*.

ANALYSIS.—The analysis of milk is attended with considerable difficulties. It is almost impossible to obtain a perfectly dry residue by evaporation, since the casein, saturated with fat, forms crusts which are impermeable to steam, and these are often burst asunder, thereby occasioning loss. The casein is not completely precipitated by acetic acid, part remaining in solution; neither does dried casein part with all its fat to ether.

The *casein* may be approximately estimated by evaporating milk on a water-bath or in *vacuo*, almost to dryness, adding acetic acid, and extracting the dried residue successively with ether, alcohol, and water (Scherer and Dumas)—or one-fifth of its weight of powdered gypsum is stirred up with the milk before evaporation, whereby spitting is avoided, the casein becomes insoluble in all solvents, and the dried residue is rendered easily pulverisable. The *fat* may then be extracted by ether and alcohol. The solid residue is determined by evaporating 1 to 3 grammes of milk in *vacuo*, or in a water-bath, and drying the residue in an air-bath, or in *vacuo* at 120°. In order to determine the *ash*, the dried substance must be ignited in oxygen gas. (Haidlen.)

Sugar.—The milk for this purpose must not be acid. To determine the sugar, the liquid may be employed which is left when casein is precipitated by sulphate of magnesium or chloride of calcium, and the excess of base precipitated by potash; or the alcoholic extract obtained in Haidlen's method of estimating casein may be used. The amount of sugar is determined by Fehling's sugar-test, or by polarised light.

Baumhauer (*J. pr. Chem.* lxxiv. 145; Jahresb. 1861, p. 873) evaporates the milk in paper-filters nearly filled with pure sand or pulverised quartz, previously well-washed with hydrochloric acid and ignited. The filters are first dried by exposing them to a current of air at 110°, on a stand of peculiar construction which allows the

entire surface of the paper to be exposed to the action of the air; 10 c. c. of each sample of milk is then poured upon them, taking care to distribute the milk uniformly over the surface of the sand and not to wet the outer edge. The stand with the filter is then exposed in the drying chamber to a current of air heated to 60°—70°, till the escaping air no longer deposits moisture, after which the temperature is gradually raised to 105° and kept at that point for half an hour, and the filters are finally left to cool for an hour over chloride of calcium, and weighed: this determines the total amount of solid constituents in the milk. To estimate the fat, the dried filters are drenched with anhydrous ether in funnels closed at top with glass plates and having their beaks provided with spring-clamps; the ether after half an hour's digestion is allowed to run by opening the spring-clamps, this operation being twice repeated, and the filters are rinsed two or three times with ether, then dried and weighed; the ether gives the quantity of fat. The sugar and soluble salts are next dissolved out in a similar manner with warm water (about 90 c. c.), and the total quantity of matter thus removed is determined by again drying and weighing the filter. The quantity of sugar in the aqueous solution is then determined by titration with a standard ferric solution, and the difference gives the amount of soluble salts. The sum of the amounts of fat, sugar, and soluble salts, deducted from the total quantity of solid matter previously determined, gives the quantity of insoluble salts and casein (the casein is, however, slightly soluble). To determine the total quantity of inorganic constituents, a known quantity of the milk (slightly acidulated with acetic acid) is evaporated to dryness over the water-bath and the residue is concentrated.

The following are analyses of human milk at different periods after child-birth, also of the milk of different animals.

Human milk.

Ewe's milk is thus the richest of all milks; that of the goat is but little inferior to human and cow's milk stand pretty close to one another, and hence the last may be easily substituted for the first; cow's milk is, however, decidedly richer in casein and sugar than that of the ass and mare are the poorest of all; they contain very small quantities of fat and of casein, but are proportionally richer in sugar. The milk of the pig differs from that of the herbivora by an almost total absence of sugar and a proportion of fat.

Fourteen analyses made at different periods, with the milk of the same woman: the soluble salts were weighed with the casein, the soluble with the sugar; they are constant.

Will's, Jahrb. 1858, 564.

Constituents of Milk.

Casein (see i. 810). Simon found 4.0 per cent. casein in human colostrum, and 2.18 per cent. in the milk six days after delivery. Milk varies in composition at different stages of the day. In the case of two cows fed with hay, oat-straw, beet-root, oil-cake, and bean-pods, the milk obtained in the morning (4 a.m.) contained 2.56 and 2.61 per cent. casein; mid-day, 2.23 and 2.38 respectively. In another case, the milk contained, in the morning, 2.24 and 2.25; at mid-day, 2.37 and 2.36; in the evening (7 p.m.), 2.70 and 2.71 per cent. casein respectively (Struckmann and Hudeker). Heynsius found the first portion of cow's milk richer in casein than the last portions. According to Vernois and Becquerel, the amount of casein in human milk varies directly with the quantity yielded; in cow's milk, inversely as the quantity. The milk of brunettes contains about 0.3 per cent. more casein than that of blondes. Women of feeble constitution yield almost normal milk, while those of vigorous constitution yield milk poorer in casein. In acute diseases, out of 19 cases, the average percentage of casein was 5.040 per cent. (3.291—5.671); and in 27 cases of chronic diseases, 3.267 per cent. (2.621—3.989) (Vernois and Becquerel). The milk of nurses between 16 and 20 years old contains 5.574 per cent. casein and extractive matter; 20—25, 3.873 per cent.; 25—30, 3.653 per cent.; 30—35, 4.233 per cent.; 35—40, 4.207 per cent.

An albuminous substance has been met with in milk, and especially in colostrum, which is not coagulated by rennet, but is precipitated by boiling. This is supposed to be *albumin*. G. Veit remarked that the colostrum of women, up to the third day after delivery, coagulated entirely or in part on heating. It afterwards lost this property. The filtrate obtained from the acid colostrum of the cow, after adding chloride of sodium, gave no turbidity with acetic acid, but yielded a precipitate with tannin, with alcohol, and by heat; on adding ammonia and boiling, an abundant precipitate was formed, but the liquid remained unchanged when treated in the same way with acetic acid. Hence albumin must have been present (Moleschott). Vernois and Becquerel found, in the milk of the buffalo-cow and of the goat, 1.3 per cent. albumin. Heynsius found 0.5 per cent. albumin in cow's milk previously coagulated with acetic acid; it was precipitated by boiling; but if the milk was previously boiled and coagulated by acetic acid at 40° C., no turbidity was produced in the filtrate by acetic acid or by boiling. Albumin is also found in milk in inflammatory diseases of the mammary glands, and when it contains blood and pus. Nevertheless, it must be remarked that Scherer prepared a kind of casein from normal milk, which coagulated by heat; while canine milk sometimes becomes thick on heating, but returns to its previous state on cooling. (Dumas.)

Fat. The fat of human milk has not been examined qualitatively with any degree of exactness. The butter of cow's milk has however been more particularly investigated. Pure milk-fat is a colourless or very pale yellow substance, solidifying at 26.5°, whereupon the temperature rises to 32°. It is soft and sticky above 18°. Dissolves in 28.9 pts. of boiling alcohol of specific gravity 0.822. It readily becomes rancid on exposure to the air, yielding volatile fatty acids, and then decidedly reddens litmus. It may be completely saponified, and then yields, together with glycerin, margaric, oleic, capric, caprylic, caproic, and butyric acids, or instead of the two last, vaccinic acid (Lerch), or, according to Heintz, oleic and butic ($C^{18}H^{34}O$, melting-point = 60.75° C.), stearic, palmitic, and myristic acids (Chevreul, *Sur les Corps gras*, 1822; Bromeis, *Ann. Ch. Pharm.* xlii. 46, &c.; Heintz, *Ann. Ch. Pharm.* lxxxviii. 300, 304; Pogg. *Ann.* xc. 137). Bromeis reckons the composition of butter according to the quantities of acid found = 68 per cent. margaric, 30 per cent. oleic, and 2 per cent. peculiar butter fat; but the components of butter seem to vary considerably.

Simon found 5·00 per cent. fat in human colostrum, and, as well as Boussegault, 2·60 per cent. in the colostrum of the cow. According to L'Heritier, the milk of brunettes contains 5·63—6·48 per cent. fat, while that of blondes contains only 3·55—4·05. Vernois and Becquerel found the contrary. According to them, the percentage of fat varies with age; the milk of women from 15—20 contains 3·738 per cent.; 20—25, 2·821 per cent.; 25—30, 2·348 per cent.; 30—35, 2·864 per cent.; and from 35—40, 2·233 per cent. It increases by nearly 0·3 per cent. during the period of menstruation. The percentage of butter varies inversely as the quantity of milk produced. It decreases with imperfect nutrition.

Milk contains different proportions of fat according to the time of day at which it is obtained. The milk of a cow contained in the morning 2·17 per cent.; at midday, 2·63 per cent., and in the evening, 5·42 per cent. (Struckmann and Bödeker). It has been remarked that the first portions of milk are less rich in fat than the last portions, from which it is concluded that milk deposits cream in the udder, and that the fat-globules adhere to the sides of the milk-passages in the smaller glandular canals of the udder and teats. This difference has not been observed in human milk. Parmentier found the first portion of cow's milk three-fourths poorer in butter than the last. According to Vernois and Becquerel, the amount of fat in human milk increases during the first two months after delivery, but decreases between the fifth and sixth, as well as between the tenth and eleventh month. The kind of food has also a considerable influence on the percentage of fat in milk. The milk of a cow fed upon ordinary food contains 3·63 per cent. fat; on sesame bran, 4·87 per cent. Dumas found that canine milk was on the whole richer in fat when the animal was fed with vegetable than with animal food. In disease, Vernois and Becquerel found that the percentage of fat was sometimes increased, sometimes diminished. A consumptive cow yielded 10·73 per cent. butter. In enteritis, human milk was found to contain 3·153 per cent. fat; in pleurisy, 2·77 per cent.; in colitis, 5·412 per cent.; in delirium and fever, 0·514 cent.; typhus, 0·909 per cent.

Canine.
1·53 (Vernois and Becquerel).
2·40 (Poggiale).

The milk of brunettes contains 7·00 and 7·12 per cent. milk-sugar, that of blondes 6·45 and 6·40 per cent. (L'Heritier). According to Vernois and Becquerel, that of

brunettes contains 4.56; blondes, 4.47. Simon found 7 per cent. milk-sugar in human colostrum; in the milk six days after birth, 6.24 per cent.; afterwards the quantity decreased. The kind of food influences the percentage of milk-sugar to a certain extent. Bensch found that it almost disappeared from canine milk when the animal was fed exclusively with meat; on substituting vegetable food, the quantity of milk-sugar increased considerably. Poggiale found in the milk of a bitch fed with meat and bread, 2.89 per cent. milk-sugar, but after the animal had been fed exclusively on meat for 21 days, only 1.82 per cent. According to the observations of Simon and of Vernois and Becquerel, rich or poor nourishment does not sensibly affect the percentage of lactin; it varies as the quantity of milk. The milk of women from 15 to 20 years old contains 3.523 per cent. milk-sugar; from 20—25, 4.472 per cent.; 25—30, 4.577 per cent.; 30—35, 3.953 per cent.; 35—40, 3.960 per cent. In the first month after birth, the quantity of sugar in the milk decreases, but it increases considerably from the eighth to the tenth month (Vernois and Becquerel). The milk of a cow yielded in the morning 4.30 per cent. sugar; at midday, 4.72 per cent.; in the evening, 4.19 (Struckmann and Bödeker). Heynais found that the last portions of cow's milk contained less sugar than the first. According to Simon, Donné and others, the percentage of sugar does not sensibly vary in disease. According to Vernois and Becquerel, this is the case only with chronic diseases, whereas in 27 cases the average amount was 4.337 per cent.; in acute diseases, only 3.310 (19 cases).

Salts. The soluble salts of milk consist of chloride of sodium, chloride of potassium, alkaline phosphates, and soda and potash combined with the casein; the insoluble, of phosphates of calcium and magnesium, chiefly combined with casein; sulphuric acid and ammonia-salts are not contained in fresh milk. Haidlen, Scheven, and others have found a little ferric oxide in milk.

Percentage of Ash in different kinds of Milk.

<i>Human.</i>		<i>Sow.</i>
0.16—0.25 (most chemists).		1.00 (Scheven).
0.138 (0.055—0.338) (Vernois and Becquerel).		
<i>Cow.</i>		<i>Ass.</i>
0.55—0.85		0.52 (Vernois and Becquerel).
0.66 (Vernois and Becquerel).		
<i>Bitch.</i>		<i>Mare.</i>
1.2—1.5		0.52 (Vernois and Becquerel).
0.78 (Vernois and Becquerel).		
1.63—2.08 (Poggiale).		
<i>Goat.</i>		<i>Sheep.</i>
0.62 (Vernois and Becquerel).		0.72 (Vernois and Becquerel).

Vernois and Becquerel found in the milk of women from 15—20 years old, 0.180 per cent. ash; 20—25, 0.143; 25—30, 0.146; 30—35, 0.144; 35—40, 0.106 per cent.

The milk of a cow yielded in the morning 0.83 per cent. ash; at midday, 0.72; and in the evening 0.78 (Struckmann and Bödeker). Heynais found slightly less ash in the last than in the first portion of cow's milk; but the soluble and insoluble salts remained in the same relations to one another. The first portions contained 0.78 per cent. salts; the last, 0.69 per cent. Vernois and Becquerel found that the percentage of salts increased both in chronic and in acute diseases (0.173 and 0.153 per cent.); in acute enteritis, 0.174 per cent.; acute pleurisy, 0.079; typhus, 0.220.

The quantity of soluble salts is generally nearly the same as if insoluble. In human milk were found 0.4—0.9 per cent. soluble salts; in cow's milk, 0.21 per cent. soluble, and 0.28 per cent. insoluble salts. According to Weber's analysis, the ash of cow's milk contains 14.18 per cent. chloride of potassium, 4.74 per cent. chloride of sodium, 23.46 per cent. potash, 6.96 per cent. soda (combined with phosphoric, sulphuric (?) and carbonic acids), 28.4 per cent. phosphoric acid, 17.24 per cent. lime, and 2.20 per cent. magnesia. Almost all the phosphoric acid is tribasic. Vernois and Becquerel found in the ash of human milk 6.9 per cent. carbonate of calcium, 70.6 per cent. phosphate of sodium, 9.8 per cent. chloride of sodium, 7.4 per cent. sulphate of sodium, and 3.8 per cent. of other salts.

Milk, at least that of the cow, contains *alkaline carbonates*. When milk is treated with acetic acid, it evolves more gas (carbonic acid) in vacuo than the same milk without acid. (Lehmann.)

The amount of *extractive matter* in milk, as well as its nature, is unknown.

Lactic acid is not supposed to exist in fresh milk. Whether the milk owes its occasionally acid reaction to lactic or butyric acid, or to acid phosphates, is uncertain.

Rees found *urea* in the milk of a woman suffering from albuminuria; also Picard, in the milk of a woman whose urine contained no albumin.

Free *gases*, especially carbonic acid, are always present in fresh milk. (Lehmann.)

Lehmann considers *albumin* to be an abnormal constituent of milk.

Marchand found *hematin* dissolved in the milk of a sick cow, but no blood cells.

Glucose appears to pass into the milk from the blood, but converted into lactic acid; iodide of potassium and free iodine pass into the milk.

Milk is coagulated by acids, alum, and various other salts; also by tannin, alcohol, and wood-spirit.

Colostrum generally forms a turbid, yellowish liquid resembling soap-suds, of sticky consistence and strongly alkaline reaction. It undergoes lactic fermentation more easily than milk, and contains more solid constituents; in the milk of cows, asses, and goats, casein is chiefly in excess; in human milk, lactic acid. It contains albumin to a considerable amount. Vernois and Becquerel found in human colostrum 1—6 days after delivery, 12.28 per cent. solid residue (4.54 per cent. casein, 3.58 per cent. fat, 4.01 per cent. lactic acid, and 0.16 per cent. salts). Simon found 16 per cent. solid residue in the colostrum of a cow, and 14 to 15 per cent. in the milk. Crusius found in the colostrum of a cow immediately after calving, 38.4 per cent. dry residue; the next day, 30.1 per cent.; the second day, 23.1 per cent.; and afterwards in the milk, 12.5 per cent.

Human milk is more bluish than cow's milk and has a sweeter taste, reacts strongly alkaline, and acidifies less easily than other milks. Specific gravity = between 1.030 and 1.034 (1.02561 and 1.04648, Vernois and Becquerel). It contains from 11 to 13 per cent. solid constituents. It is less easily and completely coagulated by rennet, the coagulum is not so gelatinous, nor so firm and solid as that of cow's milk, and it is also more digestible. Its fat contains more elain than common butter. Healthy children of both sexes discharge from the seventh to the twelfth day of their birth a white secretion from the breast (*Hæcymilch*), either alkaline or neutral, and containing milk, but no colostrum-globules. According to Guillot, this secretion has pretty much the composition of human milk.

Cow's milk has generally a pure white or yellowish-white colour. Its specific gravity varies between 1.030 and 1.039 (Simon), 1.0302 and 1.0396 (V. and B.). It contains on an average between 13 and 14 per cent. solid matter (12.29—16.5).

Mare's milk is white. Specific gravity = between 1.034 and 1.045 (1.0203, Clemm; 1.0337, V. and B.). It yields 16.2 per cent. (0.57, V. and B.) solid residue.

Ass's milk is white; sweeter than cow's milk. Specific gravity between 1.023 and 1.035 (= 1.0346, V. and B.). Contains between 9.16 and 9.53 per cent. solid matter (10.99, V. and B.). It readily turns acid, and easily undergoes alcoholic fermentation.

Goat's milk is white, of insipid sweetish taste and peculiar odour. Specific gravity about 1.036 (1.0325, V. and B.). Contains between 13.2 and 14.5 per cent. solid residue (15.51, V. and B.). On coagulation, its casein forms thick clots.

Ewe's milk is thickish, white, of agreeable taste and smell. Specific gravity = between 1.035 and 1.041. Contains 14.38 per cent. (16.77 per cent., V. and B.) solid constituents.

Sow's milk contains between 14.61 and 11.83 solid matter.

Canine milk is rather thick, and becomes thicker on warming when it does not coagulate. Specific gravity = between 1.033 and 1.036. Contains between 22.48 and 27.46 solid residue. On evaporation, the latter is converted into grape-sugar, and the solid residue absorbs much oxygen from the air. (Bensch.)

The milk of women confined for the first time, contains more water than the milk of women who have had several children. The milk of cows varies much according to the locality; that of cows in the neighbourhood of Paris contains from 3.6 to 3.7 per cent. fat; of Tyrolean, Swiss and Dutch cows, between 7.0 and 9.8 per cent. The composition of cow's milk in the first, third, fourth, fifth and sixth months is pretty much the same, varying between 12.27 and 14.20 per cent. solid matter. In the first month it contains 13.20 per cent. residue, 4.80 per cent. casein, 4.25 per cent. butter, 3.57 per cent. lactic acid, and 0.66 per cent. salts; in the second month, 17.32 per cent. solid residue, 5.81 per cent. casein, 7.06 per cent. butter, 3.87 per cent. lactic acid, and 0.57 per cent. salts; in the eighth month, 24.73 per cent. residue, 11.50 per cent. casein, 4.41 per cent. butter, 7.67 per cent. lactic acid, and 1.16 per cent. salts. (Vernois and Becquerel.)

The milk of a consumptive cow yielded a large quantity of cream, but did not coagulate either by rennet or on boiling. It contained 24.97 per cent. solid residue, 10.13 per cent. casein and insoluble salts, 10.73 per cent. butter, 4.09 per cent. lactic acid, and soluble salts.

Milk is the most indigestible of all uncoagulated albuminoids; its solubility in the gastric juice depends upon the consistence of its coagulum. Human milk is more readily digested than cow's milk. Frerichs found that 24 hours after he had fed a dog with milk, all had disappeared from the stomach except a few flakes, very rich in fat. Milk introduced into the stomach was instantly coagulated, and the serum was rapidly absorbed, while the coagulum formed bulky and more or less hard clots. The digestion of milk does not begin, properly speaking, until the liquid portion has been absorbed.

Thomson has shown that the percentage of fat in milk is in no way dependent upon the amount of sugar in the food.

Bensach has remarked, and his experiments have been confirmed by Poggiale, that the milk of bitches fed exclusively on meat still contained milk-sugar, showing that sugar is formed in the organism from albuminoids.

Cow's milk contains 30 pts. unnitrogenised substances for every 10 plastic; human milk 40 pts. unnitrogenised for every 10 plastic (Liebig). Cow's milk contains 3.78 per cent. nitrogen; human milk 1.59 per cent. A cow yields in 24 hours about 6½ litres or about 6 kgr. of milk.

With respect to the generation of milk, Lehmann and others do not suppose that the constituents of milk are derived directly from the blood. Neither casein nor lactic acid has been detected in blood. The sugar of blood is fermentable. Fat might transude from the blood, but it is not probable that it does so; since cholesterin, which transudes with much facility, is not found in milk, and little if any butyric acid in blood. The composition of the milk-salts also differs widely from that of the salts of blood-serum.

Tests for milk: adulterations.—Fresh milk ought not to change its appearance on boiling. Sour milk deposits clots, or partly coagulates on boiling. A simple instrument, called a lactometer, for roughly estimating the amount of cream in milk, has been constructed by Banks. It consists of a glass tube having an internal diameter of 4 centimetres, and about 17 centimetres high. A circular ring scratched on the glass indicates a capacity of two decilitres. Above this line 30 small divisions are made, each indicating $\frac{1}{300}$ th of the total capacity of the vessel up to the highest division marked 0°. The vessel is filled up to 0° and allowed to stand for 24 hours; the thickness of the stratum of cream may then be read off. Another method is that of Donné. He has invented an instrument called a galactoscope, which measures the opacity of milk; the greater opacity indicating more fat-globules, and thus a greater amount of butter. It consists of a tube with a glass plate fitted at one end, and at the other a movable glass plate. The milk is introduced by means of a small funnel, and the tube is lengthened by screwing out the movable plate until the liquid no longer transmits the light of a lamp placed at a certain distance. The plate is then screwed in until the light of the lamp is rendered just visible. According to Donné, milk which removes the plate by 27°, indicates 3.627 per cent. butter; 31°, 2.89 per cent. butter. 40° to 36° of the galactoscope = 5 per cent. cream (poor milk); 35° to 30° = 5.10 per cent. cream (common milk); 30° to 25° = 10 to 15 per cent. cream (good milk); 25° to 20° = 15 to 20 per cent. cream (very rich milk); and 20° to 15° indicates an exceedingly rich milk, the last portion from the cow.

The most common adulterations of milk are the following:—Milk obtained the day before is creamed, in order to sell the cream separately; sometimes the creamed milk is mixed with fresh milk, and about half its own volume or more of water is added to the mixture. Sometimes a colouring matter, such as brown extract of chicory, caramel, &c., is added to disguise the bluish colour of milk thus adulterated. The colouring matter remains in the serum when the milk is coagulated, and may then be detected (Payen). Flour, starch, and finely-powdered chalk are also used to adulterate milk. As the chalk readily subsides, it may then be recognised by its effervescing with hydrochloric acid. The starch-granules may be readily detected under the microscope, and distinguished from the milk-globules; if a polarising apparatus be adjusted to the microscope, each of the granules will appear marked with a black cross. The addition of tincture of iodine will also indicate the presence of starch, by imparting to it the characteristic blue colour. The macerated brains of sheep and other animals are said to be sometimes added to milk. In this case, the microscope would readily detect the presence of fragments of nerve and other organised structures, which are not present in pure milk. The addition of water is not so easily detected, since if cream has been taken from the milk, its specific gravity will increase, while the addition of water again lowers it. It may however be detected by the galactoscope, if no starch or

brains have been added. The milk of diseased animals is sometimes solid, and has a disagreeable taste and smell, as well as a slightly viscid appearance. Mucus globules will be detected in it under the microscope.

According to Baumhauer (*loc. cit.*) all determinations of the comparative purity of milk by instruments like those above described, are very inaccurate; he gives as the result of determinations made by his own method above described (p. 1016), that all milk may be regarded as adulterated with water, which gives less than 110 grms. of solid residue per litre (or 1928 grs.—about 3 oz. troy—per quart). The minimum quantity of butter in normal cow's milk is 22 grms. per litre (or 395 grs. per quart). Milk may be regarded as creamed, when the proportion of butter is less than $\frac{1}{3}$ th of the total weight of solid matter.

Further information will be found in the following works:

Paris, 1857, p. 195. See also the several volumes of Kopp's *Jahresbericht*. C. E. L.

MILK QUARTZ. See QUARTZ.

MILK-SUGAR. $C^{12}H^{22}O^{11}$.—Called *Lactin* by Pasteur, *Lactose* by Dumas. Pasteur, on the other hand, applies the term *lactose* to a product of the decomposition of milk-sugar (see p. 1022).

This compound, the saccharine constituent of milk, was first prepared by Fabrizio Bartholetti, in 1619, from whey, thence called *Manna* or *Nitrum serilactis*, and afterwards, *Galactium Bartholetti*. It has been chiefly examined by Bouillon Lagrange and Vogel (*J. Phys.* lxxii. 208), Berzelius (*Ann. Chim.* xcv. 67), Bensch (*Ann. Ch. Pharm.* lxi. 221), Vohl (*ibid.* lxx. 360), Winckler (*Repert. Pharm.* xlii. 46), Krause and Städeler (*Mitth. d. naturf. Gesellsch. in Zürich*, 1854, p. 473), Lieben (*J. pr. Chem.* lxxvii. 407), Pasteur (*ibid.* lxxviii. 427), Dubrunfaut (*ibid.* lxxviii. 422), Luboldt (*ibid.* lxxvii. 282), and Berthelot (*Ann. Ch. Phys.* [3] liv. 82; lx. 98); see also Gm. xv. 217; Gerh. ii. 563.

Milk-sugar has been found only in the milk of mammalia; it may, however, have been confounded in some cases with glucose, the presence of which has been detected in the blood, in the liver, and in the eggs of birds. It has not yet been formed artificially from any other compound.

It is extracted by treating milk with dilute sulphuric acid, or calf's rennet, to precipitate the curd, then filtering, and evaporating the whey to the crystallising point. This product is purified by treatment with animal charcoal and repeated crystallisation; finally, according to Krause and Städeler, by repeatedly precipitating the aqueous solution with alcohol. In some localities, especially in Switzerland, milk-sugar is prepared on the large scale from the whey obtained in the fabrication of cheese.

Milk-sugar is deposited from its aqueous solution in hemihedral trimetric crystals, exhibiting the combination $\alpha \tilde{P} \infty \cdot \frac{P}{4} \cdot oP \cdot 2\tilde{P} \infty$. Angle $oP : 2\tilde{P} \infty = 109^\circ 39'$; $oP : \frac{P}{4} = 101^\circ 41'$. Ratio of axes, $a : b : c = 0.6215 : 1 : 0.2193$ (Schabus). It is white, semi-transparent, hard, and grates between the teeth. The crystals, which contain $C^{12}H^{22}O^{11} \cdot H^2O$, do not give off any water at 200° , but the whole, amounting to 5.08 per cent. (1 at. = 5.00 per cent.) at 130° , or more quickly between 140° and 150° . The anhydrous milk-sugar which remains, forms a colourless melted mass, which solidifies in the crystalline state on cooling.

Crystallised milk-sugar is slightly hygroscopic, and dissolves in 5 or 6 pts. of cold, and $2\frac{1}{2}$ pts. of boiling water. The saturated solution produced by prolonged contact of water with excess of milk-sugar at 10° , has a density of 1.055, contains 14.56 per cent. crystallised milk-sugar, and when left to evaporate, begins to deposit crystals as soon as it attains the density of 1.063 and contains 21.64 per cent. milk-sugar. The aqueous solution turns the plane of polarisation to the right. Dextro-rotatory power for the transition-tint, $[\alpha] = 59.3^\circ$ (Berthelot); 60.28° (Biot). According to Poggiale, 201.9 pts. of milk-sugar produce the same deviation as 164.7 pts. cane-sugar. The dextro-rotatory power of a recently prepared solution of milk-sugar is greater in the ratio of 8 : 5, than that of the same solution after standing for some time or after being heated. The rotatory power diminishes slowly at 0° , more quickly on heating, and at the boiling heat it diminishes in two minutes to 56.4° for crystallised milk-sugar. (E. O. Erdmann, *Jahresb.* 1856, p. 671.)

Milk-sugar is insoluble in alcohol and in ether, but dissolves readily in distilled vinegar, crystallising out unaltered on evaporation.

Decompositions.—1. Dry milk-sugar turns brown when heated to about 160° , without fusing, and at 175° gives off water, and yields lactocaramel, $C^{12}H^{20}O^6$. At 203° it melts, and at a higher temperature yields humus-like substances.—2. Milk-sugar boiled with dilute sulphuric acid is converted into lactose (*vid. inf.*); the same transformation appears also to be produced by prolonged boiling with water.—3. Strong sulphuric or hydrochloric acid, and alkalis, decompose it, especially when heated, with formation of brown or black products.—4. Milk-sugar is easily decomposed by oxidising agents. It reduces metallic silver from silver-solutions (Liebig, Ann. Ch. Pharm. xcviii. 132). A solution of milk-sugar mixed with potash dissolves cupric hydrate, forming a deep blue solution which deposits cuprous oxide, even in the cold. From a solution of potassio-cupric tartrate, it throws down a smaller quantity of cuprous oxide (about $\frac{1}{5}$), than glucose (ii. 860). Distilled with oxidising mixtures, such as sulphuric acid and peroxide of manganese, it yields formic acid. With nitric acid, it forms mucic, saccharic, tartaric, and a small quantity of racemic acid, and finally oxalic acid.

Very strong nitric acid or a mixture of nitric and sulphuric acids converts milk-sugar into a substitution-product called nitro-lactin, which is precipitated from the acid solution by water, and crystallises from alcoholic solution in nacreous laminae detonating when heated. (Reinsch; Vohl, Jahresh. 1849, p. 470.)

When milk-sugar is heated to 100° for some hours with bromine and water, there is formed, probably by direct addition of bromine, a brominated compound, which when decomposed by bases, yields isodiglycolethylene or lactonic acid (p. 414).

Milk-sugar is not brought immediately by yeast into the state of alcoholic fermentation; but when it is left for some time in contact with yeast, fermentation gradually sets in. When cheese or gluten is used as the ferment, the milk-sugar is converted into lactic acid (ii. 631; iii. 455). Alcohol is, however, always formed at the same time, especially if no chalk is added to neutralise the acid as it forms; the quantity of alcohol formed is greater also as the solution is more dilute.

Combinations.—Milk-sugar unites with bases, but the compounds have not been much examined. It differs from glucose, in not forming a definite compound with chloride of sodium. It absorbs about 12.5 per cent. ammonia-gas, which, however, it again gives up on exposure to the air. It dissolves in strong caustic potash, forming a thick liquid from which alcohol throws down white flocks containing 12.4 per cent. H^2O . The compound is easily decomposed by acids, even by carbonic acid, the milk-sugar separating from it unaltered. With soda a similar compound is formed, containing 8.3 per cent. soda.

Milk-sugar dissolves easily in milk of lime, forming a solution in which alcohol produces turbidity, and if the liquid is concentrated, throws down a white precipitate containing, when washed and dried, from 11.2 to 16.7 per cent. lime. Baryta forms a similar compound containing 40.1 pure baryta.

Milk-sugar gently heated with oxide of lead, gives off water. On digesting the aqueous solution with lead-oxide, at a temperature below 50° , part of the oxide dissolves, and an insoluble compound remains suspended, containing when dried 63.5 per cent. lead-oxide. The dissolved portion evaporated in a vacuum leaves a gummy soluble mass, containing 18.1 per cent. lead-oxide: ammonia added to the solution throws down an insoluble compound.

Estimation of Milk-Sugar. Milk-sugar may be estimated like glucose (ii. 865). Poggiale (Compt. rend. xxviii. 505) prepares the test-liquor by dissolving 10 grms. of cupric sulphate, 10 grms. of cream of tartar, and 30 grms. caustic potash in 200 grms. distilled water. The filtered liquid, which has a deep blue colour, is titrated by determining the amount of pure milk-sugar required to decolorise a given volume of it. To determine the quantity of sugar in milk, it is necessary, in the first place, to separate the fat and the casein (p. 1016). Milk-sugar may also be estimated by its rotatory power.

Products of the Transformation of Milk-sugar.

1. **LACTOSE or GALACTOSE**, $C^6H^{12}O^6$ (Pasteur, Compt. rend. xlii. 347). A kind of sugar isomeric with glucose, and bearing considerable resemblance to it, produced by boiling milk-sugar for several hours with 4 pts. of water and 2 per cent. sulphuric acid, neutralising with chalk, evaporating the filtrate to a syrup, and then leaving it to crystallise.

Lactose crystallises more readily than grape-sugar, in nodules consisting of microscopic, limpid, rectangular prisms acuminate at the ends,—more generally of six-sided, round-edged laminae having a pen-shaped protuberance in the middle. Dextro-rotatory power for the transition tint, $[\alpha] = 83.22^{\circ}$ at 15° ; in the recently prepared

solution it is stronger, $[a] = 139.66^\circ$, but sinks to the former magnitude slowly at ordinary temperatures, instantly on boiling.

Lactose dissolves in water, does not combine with *chloride of sodium*, and dissolves but very sparingly in cold alcohol.

Lactose yields with *nitric acid* twice as much mucic acid as milk-sugar. From an alkaline solution it reduces as much *cupric oxide* as grape-sugar. It ferments in contact with *yeast*. If the fermentation be interrupted before it is complete, the liquid still contains unaltered lactose, which therefore has not undergone any division or further alteration during the fermentation. In this fermentation the same products are formed as in the fermentation of cane-sugar. (Pasteur, Ann. Ch. Phys. [3] lviii. 356.)

2. LACTOCARAMEL, $C^6H^{10}O^5$. Produced when milk-sugar is heated for some time to 180° . It is a dark brown substance, soluble in water, insoluble in alcohol, and capable of combining with the oxides of lead and copper. (Lieben, Wien. Akad. Ber. xviii. 180; Gm. xv. 227.)

3. GALLACTIC and PECTOLACTIC ACIDS. These names are given by Bodeker and Struckmann (Ann. Pharm. c. 264) to two acids produced when milk-sugar is oxidised in alkaline solution by cupric oxide. Both are syrupy, and form uncrystallisable salts, respecting the supposed composition of which, see Gm. xv. 229.

4. NITROLACTIN is best prepared by treating milk-sugar with a mixture of nitric and sulphuric acid, and precipitating with water. It crystallises from alcoholic solution in nacreous laminae, which detonate when heated.

MILLERITE. Native sulphide of nickel. (See NICKEL.)

MILLINGTONIA. The bark of *Millingtonia hortensis* L., used in Java as a remedy against fever, contains, according to R. Hollandt (Jahresb. 1861, p. 767)—besides starch, gum, sugar, fat, wax, and an iron-greening tannin—a small quantity of a bitter substance, and certain bodies described as humic acid, to which the formulae $C^{34}H^{28}O^{24}$ and $C^{14}H^{11}O^{12}$ are assigned.

MILOSCHIN. A compact chromiferous mineral, probably a mechanical mixture, containing, according to Kersten (Pogg. Ann. xlvii. 485), 27.50 per cent. silica, 45.01 alumina, 3.61 chromic oxide, 0.30 lime, 0.20 magnesia, and 23.30 water (= 99.92). Colour indigo-blue to celandine-green. Hardness = 2. Specific gravity = 2.13. Yields water when heated in a tube. Infusible before the blowpipe; partly dissolved by hydrochloric acid. Found at Rudniak in Servia, associated with quartz and brown iron ore.

MIMETESITE. *Mimetena*. *Mimetite*. *Green Lead-ore*. *Traubenblei*. Varieties: *Kampylite*, *Hedyphane*.—This name is applied to several minerals, isomorphous with pyromorphite, consisting either of pure arsenato-chloride of lead, or of isomorphous mixtures of this compound with the corresponding phosphato-chloride, and with the analogous calcium-compounds. The crystals are hexagonal prisms, exhibiting the combinations $P \cdot oP$ (fig. 239, ii. 739), $P \cdot \infty P \cdot oP$ (fig. 240), $\infty P \cdot oP \cdot 2P_2$ (fig. 241), and $P \cdot oP \cdot \infty P \cdot \infty P_2$. Length of principal axis = 0.7392. Angle $P : P$; (terminal) = $142^\circ 7'$; (lateral) = $80^\circ 25'$. Cleavage imperfect parallel to P and ∞P . Hardness = 3.5. Specific gravity = 7.19 to 7.35, *mimetene*; 5.3 to 5.5, *hedyphane*; 5.8 to 6.9, *kampylite*. Lustre resinous. Colour pale yellow passing into brown, sometimes orange-yellow (*kampylite*) from the presence of chromate of lead; sometimes whitish when containing much calcic phosphate (*hedyphane*). Streak white or nearly so. Subtransparent to subtranslucent. Sectile. Melts before the blowpipe on charcoal, but less easily than pyromorphite; exhibits a crystalline surface on cooling, and is easily reduced to lead-globules with evolution of arsenical fumes. Soluble in nitric acid and in potash.

Analysis.—a. From the Azulaques mine near La Blanca, Zacatecas, Mexico: yellow needle-shaped crystals on wulfenite (Bergemann, Pogg. Ann. lxxx. 401).—b. Phoenixville, Chester County, Pennsylvania: colourless or yellow crystals (Smith, Sil. Am. J. [2] xx. 342).—c. Johann-Georgenstadt: yellow crystallised (Wöhler, Pogg. Ann. iv. 161).—d. Caldbeck-fell, Cumberland (Breithaupt's *kampylite*) (Rammelsberg, *ibid.* xci. 316).—e. Hohnhausen in Saxony (Dufrénoy, *Traité de Min.* iii. 46).—f. Cornwall (Dufrénoy, *loc. cit.*).—g. Preobrazjansk mine, Siberia: crystals yellow within, but black on the outside, from a coating of pyrolusite (Struvé, *Rammelsberg's Mineralchemie*, p. 382).—h. Långbanshytta, Sweden (Breithaupt's *hedyphane*): massive, greyish-white (Kersten, Schw. J. lxi. 1).—i. Mina Grande, near Arqueros in Chile: yellow, earthy. (Domeyko, Ann. Min. [4] xiv. 145.)

I. Containing only Arsenic Acid.

Cl.	As ² O ⁵ .	PbO.	
2.44	23.06	74.96	= 100.46.

III. *Containing Lime.*

	Cl.	As ² O ₃ .	P ² O ₅ .	V ² O ₅ .	PbO.	CaO.	CuO.
h.	2.66	22.78	not determined	.	51.03	14.09	
i.	2.41	12.06	5.36	1.04	68.46	8.31	0.96 = 99.50.*

The mineral I. is a compound of chloride of lead and pure triplumbic arsenate, $\text{PbCl}_2 \cdot 3\text{Pb}^2\text{As}^2\text{O}^6$.

Those included under II. are isomorphous mixtures of true mimetosite and pyromorphite (phosphato-chloride of lead) represented by the formula $\text{PbCl}_2 \cdot 3\text{Pb}^2(\text{As}; \text{P})^2\text{O}^6$.

In the two minerals included under III., the lead is partly replaced by calcium; the composition of h may be nearly represented by the formula $\text{PbCl}_2 \cdot 3 \left[\begin{smallmatrix} 3\text{Pb} \\ 2\text{Cu} \end{smallmatrix} \right] \left[\begin{smallmatrix} 3\text{As} \\ 3\text{P} \end{smallmatrix} \right] \text{O}^6$.

The earthy mineral from Chile appears to be hedyphane mixed with a little vanadate of lead.

MIMOSA or ACACIA GUM. See GUM (ii. 953).

MIMOTANNIC ACID. Syn. with CATECHU-TANNIC ACID (i. 817).

MINDERERI SPIRITUS. Acetate of Ammonium (i. 13).

MINERAL. This term, in its widest sense, denotes any substance not formed by the processes of organic life; in its more restricted and more usual sense, it signifies any homogeneous solid or liquid inorganic body, formed by natural processes, without the concurrence of art. Minerals understood in this sense, constitute the essential part of the earth's crust. It is usual, however, to include under the same general denomination, several substances which are evidently the remains of organised beings, chiefly vegetables, which lived upon the earth in former ages, e.g. coal, lignite, amber, and the several varieties of fossil resins and bitumens. Such bodies should perhaps in strictness be called fossils, but they are more usually classed with minerals, and described as such in works on Mineralogy.

MINERAL ACIDS are acids of inorganic origin, either existing ready formed in natural minerals, or formed from inorganic materials by artificial processes. The term is chiefly applied to the stronger acids, sulphuric, nitric, phosphoric, hydrochloric, &c.

MINERAL ALKALI. An old name of Soda. (See ALKALI, i. 115.)

MINERAL BLUE. A term sometimes applied to Prussian blue when mixed with certain white substances, such as clay, heavy spar, gypsum, &c., which give it a light blue colour.

MINERAL CAOUTCHOUC. Syn. with ELATERITE (ii. 374).

MINERAL CHAMELEON. Manganate of potassium (p. 818).

MINERAL GREEN. Scheele's green. (See GREEN PIGMENTS, ii. 914.)

MINERAL INDIGO. A term applied by Keller to the blue oxide of molybdenum, formed by the reducing action of tin or stannous chloride on recently precipitated molybdic acid. (See MOLYBDENUM, p. 1036.)

MINERAL KERMES. Amorphous Trisulphide of Antimony (i. 330).

MINERAL OIL PITCH, RESIN. (See PETROLEUM.)

MINERAL PURPLE. Gold-purple or Purple of Cassius (ii. 938).

MINERAL TALLOW. Syn. with HATCHETTIN (p. 14).

MINERAL TURPETHUM. Mercuric sulphate. (See SULPHATES.)

MINERAL WATERS. See WATER.

MINERAL YELLOW. A term sometimes applied to the yellow oxychlorides of lead, used as pigments (p. 556).

* After deduction of 1.1 alumina and ferric oxide, 2 clay, and 1.12 water.

MINNETTE. An eruptive rock occurring in the Vosges, where it forms small veins chiefly in granite and syenite. It consists of mica (the characteristic constituent) varying in colour from brownish-black to greenish, and orthoclase imbedded in a felspathic ground-mass. It is usually fine-grained, often porphyroidal, when the felspar crystals are well developed. The ground-mass frequently also contains greyish-green or dark green hornblende already far advanced in decomposition. The rock also contains quartz (in very small quantity), triclinic felspar, chlorite, calcspar, &c., often also crocidolite. A specimen from the Ballon d'Alsace, gave by analysis:

SiO ² .	Al ² O ³ .	Mn ² O ³ .	FeO ² .	CaO.	MgO.	K ² O.	Na ² O.*	H ² O.	CO ² .
56.96	12.95	0.65	7.58	4.63	6.62	4.35	2.22	1.44	1.94 = 99.34

(Delosse, Ann. Min. [5] x. 517; Jahresb. 1857, p. 705). A rock of similar constitution from Mittershausen in the Odenwald, has been analysed by Bunsen (Jahresb. 1861, p. 1068).

MINIUM. Red oxide of lead (p. 551).

MINJAC-TANKEAWAN or **TINKAWAN.** A solid vegetable fat obtained from the fruit of a tree growing in Borneo and Sumatra. The principal portion of it, insoluble in cold alcohol, consists, like cacao-fat, of stearin, palmitin and olein; a smaller portion, soluble in cold alcohol, contains free stearic acid, palmitic acid, and traces of a volatile fatty acid. (E. Ruge, Jahresb. 1862, p. 506.)

MIRABELLES. See FRUIT (ii. 714).

MIRABILITE. Syn. with Glauber salt. (See SULPHATES.)

MISENITE. Acid sulphate of potassium, KHSO⁴, occurring in white silky fibres in a hot tufa cavern near Misene. (Scacchi, Mem. Geol. sulla Campania, 1849, p. 98.)

MISPICKEL. Fe²As²S², *Arsenical pyrites*, *Arsenopyrite*, *Danaite*, *Plinian*, *Fer arsenical*, *prismatischer Arsenikkies*.—This mineral occurs in trimetric crystals, in which the ratio of the axes $a : b : c = 0.676 : 1 : 1.189$. Angle $\infty P : \infty P = 68^{\circ} 7'$; $\frac{1}{2} P \infty : \frac{1}{2} P \infty$ in the basal principal section = $34^{\circ} 34'$. Ordinary combination $\infty P. \frac{1}{2} P \infty$. Cleavage rather distinct, parallel to ∞P . Occurs almost columnar, compact granular, or impalpable. Hardness = 5.5 to 6. Specific gravity = 6 to 6.4. Lustre metallic. Colour silver-white inclining to steel-grey. Streak dark greyish-black. Fracture uneven. Brittle. Heated in a tube, it first yields a red or brown sublimate of sulphide of arsenic, then a black sublimate of metallic arsenic. On charcoal before the blowpipe, it melts to a black magnetic bead, which sometimes exhibits the reactions of cobalt as well as those of iron. According to Berthier, when heated in a closed crucible, it gives off half its sulphur, and a fourth of its arsenic. Nitric acid decomposes it, with separation of sulphur and arsenious acid; nitro-muriatic acid, with separation of sulphur alone, which may be completely dissolved by prolonged digestion.

Analyses. a. Freiberg (Behnke, Pogg. Ann. xcviii. 184).—b. Ehrenfriedersdorf: *Plinian* (Plattner, *ibid.* lxxvii. 127, lxxix. 430).—c. Reichenstein (Weidenbusch, *Rammelsberg's Mineralchemie*, p. 58).—d. Melchiorstollen near Jauernick in Austrian Silesia: massive (Freitag, *ibid.*).—e. Sala in Sweden (Behnke, *loc. cit.*).—f. Altenberg, near Kupferberg in Silesia: large crystals of specific gravity 6.043 (Behnke).—g. Rothschau, near Landshut in Silesia: specific gravity 6.067 (Behnke).—A. Wettin: small twin-crystals, of specific gravity 5.365 and 5.637 (Bäntsch, Zeitschr. f. d. ges. Naturw. vii. 372):

	a.	b.	c.	d.	e.	f.	g.	A.
Sulphur	20.38	20.08	19.17	21.14	18.52	20.25	19.77	22.63
Arsenic	44.83	45.46	45.94	41.91	42.05	43.78	44.02	39.86
Antimony					1.10	1.05	0.92	
Iron	34.32	34.46	33.62	36.95	37.65	34.35	34.83	37.51
	99.53	100.00	98.73	100.00	99.32	99.43	99.54	100.00

Mispickel is also found in beds at Breitenbrunn and Raschau, Andreasberg and Joachimsthal; at Tunaberg in Sweden; and at Huel-Maudlin and Unanimity in Cornwall; also at Franconia, Jackson and Haverhill in New Hampshire, and several other localities in the United States. (Dana, ii. 63.)

Danaite (ii. 303) and *Glaucodote* (ii. 846) are varieties of mispickel in which the iron is partly replaced by cobalt, to the amount of one-sixth in the former and one-third in the latter. (Dana, ii. 62.)

MISLETOE. *Viscum album*.—The chemical constitution of this plant has been examined by P. Reinsch (Jahresb. 1860, p. 541), who has found in it two viscous substances called *viscaoutchin* and *viscin* (q. v.).

* With a little lithia; a trace of copper was also found.

MISY. An impure ferric sulphate found at Rammelsberg, near Gmlar in the Harz. (See SULPHATES.)

MITIS-GREEN. Arsenate of copper, $2\text{CuO} \cdot \text{As}_2\text{O}_5$. (See GREEN PIGMENTS, ii. 944.)

MOILLONITE. Syn. with MEISONITE (p. 866).

MOCHA STONE or *Moss Agate*. (See AGATE, i. 82.)

MODUMITE or *Skutterudite*. An arsenide of cobalt, Co^3As_2 , found at Skutterud, near Modum in Norway (i. 1042).

MOHSITE. Syn. with Leucopyrite or native proto-arsenide of iron, FeAs (p. 368).

MOHSITE. Native titanate of iron. (See TITANIUM.)

MOLECULE. This term, in its strict chemical sense, denotes the smallest quantity of a compound body that can take part in any chemical reaction. Thus, as explained in the article ATOMIC WEIGHTS (i. 467-469), the molecule of water is assumed to be $\text{H}^1\text{O} = 18$ and not $\text{HO} = 9$, because, in the great majority of cases, 18 pts. by weight ($\text{H} = 1$) is the smallest quantity of water that can be taken up by, or eliminated from, any group of elements concerned in a reaction. For a similar reason, the molecule of ammonia is assumed to be $\text{NH}^3 = 17$, and not any multiple or submultiple thereof. (See Odling, Chem. Soc. Qu. J. xi. 107.)

To enter into all the considerations by which the molecular weights of bodies are determined, would be to repeat what has already been treated in some detail in other articles of this work, especially that above referred to (see also CLASSIFICATION, i. 1007). It may therefore suffice to point out in this place that, among the purely chemical considerations which enter into the determination of this point, a prominent place must be assigned to the manner in which the elements of a compound are replaced by other radicles, simple or compound. Thus, in the four typical molecules,

the hydrogen in the first, viz. hydrochloric acid, must be either wholly replaced or not at all; whereas in water, either the half or the whole of the hydrogen may be thus replaced, but no other fraction; and in ammonia, the substitution takes place by thirds; and in marsh-gas, by fourths. Again, sulphuric acid is regarded as dibasic, and represented by H^2SO_4 ; phosphoric acid as tribasic, and denoted by H^3PO_4 ; tartaric acid as tetrabasic, by $\text{H}^4\text{C}^2\text{H}^2\text{O}_6$, for similar reasons.

Physical considerations likewise enter largely into the determination of molecular weights. Thus, in compound gases and all compounds whose specific gravities can be determined in the state of vapour, the molecule is assumed to be so constituted that its weight is double of the specific gravity, that is to say, of the weight of a unit-volume of the vapour. This assumption cannot at present be said to rest on any physical basis; but it is found to be true in numerous cases in which the weight of the molecule can be fixed independently of it by purely chemical considerations; and hence it is extended to others in which such verification cannot be obtained. Other physical considerations which enter into the determination of molecular weights are specific heat, boiling point, isomorphism, &c. (See ATOMIC WEIGHTS, i. 466-473; HAAT, iii. 30-40 and 89-91; ISOMORPHISM, iii. 423-432.)

The term molecule, as applied to elements, must be understood in a somewhat different sense from that which it bears when applied to compounds. The smallest quantity of an elementary body that can enter into a reaction is called, not a molecule, but an atom; and the molecule of an element is the smallest quantity, or group of atoms, that can exist in the free state. Many considerations lead us to suppose that in the majority of cases, this group consists of two elementary atoms, the molecule of hydrogen, for example, being H_2 . (See ATOMIC WEIGHTS, i. 466; and CHEMICAL AFFINITY, i. 867.) There are also certain compound radicles, viz. the alcohol-radicles, whose molecules in the free state are generally supposed to be the methyl, ethyl, &c., whose molecules in the free state are generally supposed to be the methyl, ethyl, &c., whose molecules in the free state are generally supposed to be the methyl, ethyl, &c., whose molecules in the free state are generally supposed to be the methyl, ethyl, &c.; doubles of those by which they enter into combination; e.g., free methyl = CH_3OH^1 ; but recent investigations on the relations between these radicles and their hydrides (pp. 182, 198), have thrown considerable doubt on the existence of these particular compound molecules.

MOLYBDENUM. Symbol, Mo. Atomic Weight, 92.—A metal occurring in small quantity as a sulphide (*molybdenite*), and as molybdate of lead (*wulfenite*). The native sulphide was first distinguished from plumbago, which it much resembles, by Scheele in 1778; the metal was first prepared from the trioxide by Hjelrn in 1782. The most complete investigations of the properties and combinations of this metal have been made by Berzelius (Pogg. Ann. iv. 153; vi. 361, 369; vii. 261); Svanberg and Struve (J. pr. Chem. xlv. 257; Jahresb. 1847-48, p. 406); Struve

(J. pr. Chem. lxi. 449; Jahresb. 1854, p. 346); Blomstrand (J. pr. Chem. lxxi. 449; lxxvii. 88; lxxxii. 433; Jahresb. 1857, p. 191; 1859, p. 164; 1861, p. 239); and H. Schultze (Ann. Ch. Pharm. cxxvi. 49; Jahresb. 1863, p. 217). The name molybdenum is derived from *μολύβδαινα* or *molybdæna*, applied by Dioscorides and Pliny to galena and other lead compounds.*

Preparation.—Metallic molybdenum is prepared:—1. By exposing either of the oxides, or molybdate of ammonium, or acid molybdate of potassium, to a full white heat in a crucible lined with charcoal. The reduction is easily effected, and may even be performed on charcoal before the blowpipe with carbonate of sodium; but to obtain a fused button of the metal, a very strong heat is required (Berzelius).—2. By passing dry hydrogen gas over either of the oxides of molybdenum heated to whiteness in a porcelain tube. (Berzelius.)

Properties.—Molybdenum reduced by hydrogen is a grey pulverulent mass which acquires a metallic lustre by trituration, and conducts electricity. By fusion in a Deville's blast-furnace, it is obtained as a white mass, with nearly silvery lustre, harder than topaz, and of specific gravity 8.6. (Debray, Compt. rend. xli. 1098.)

Molybdenum is unalterable in the air at ordinary temperatures, but when slowly heated it acquires, first a brownish-yellow, then a blue tarnish, and finally takes fire (? the pulverulent metal) and burns to molybdic trioxide (Berzelius). It is rapidly oxidised by fusion with *nitre*, slowly by *hydrate of potassium*, and it is not dissolved by boiling potash-lye. It dissolves in *nitric acid* with evolution of nitrous fumes, and in hot strong *sulphuric acid* with evolution of sulphurous anhydride. If the acids are used in small quantity only, the metal is converted into molybdic oxide; with a larger proportion of sulphuric acid, the blue oxide is formed; and with a larger proportion of nitric acid the product is molybdic acid, which is also partially deposited in the solid state. Molybdenum is likewise oxidised and dissolved by *chlorine-water* and by a mixture of *nitric* with *sulphuric* or *hydrochloric acid*. It is dissolved by boiling aqueous *arsenic acid*, slightly also by *phosphoric* and *boric acids*; not by hydrochloric or dilute sulphuric acid. It reduces the oxides of *silver* and *mercury* when triturated with them. Ignited in a stream of *aqueous vapour*, it is oxidised, with separation of hydrogen.

Combinations.—Molybdenum enters into combination as a diatomic, tetratomic, hexatomic, and sometimes also as a tri-atomic radicle: thus it forms the oxides $\text{Mo}^{\circ}\text{O}$, $\text{Mo}^{\circ}\text{O}^2$, $\text{Mo}^{\circ}\text{O}^3$, the chlorides, $\text{Mo}^{\circ}\text{Cl}$ and $\text{Mo}^{\circ}\text{Cl}^2$; the bromides, $\text{Mo}^{\circ}\text{Br}^2$, $\text{Mo}^{\circ}\text{Br}^3$, the bromo-chloride, $\text{Mo}^{\circ}\text{Br}^2\text{Cl}$, the oxychloride, $\text{Mo}^{\circ}\text{Cl}^2\text{O}$, &c. Its exact position in the metallic series is not yet exactly ascertained, inasmuch as its specific heat has not been determined, and those of its compounds which are volatile, assume the gaseous state at too high a temperature to allow of the determination of their vapour-densities (see page 968).

MOLYBDENUM, ALLOYS OF. Molybdenum unites with tin, lead, iron, copper, silver, gold, and platinum, rendering them less fusible, more brittle, and, except in the case of silver, whiter. *Molybde of copper* is of a pale, copper-red colour, malleable if the molybdenum is not in excess. With 2 pts. of *gold*, molybdenum forms a black, brittle globule.—*Molybde of iron* constitutes the so-called "bears" found on the hearths of copper-furnaces (p. 368). Equal parts of molybdenum and *platinum* yield a hard, brittle, shapeless lump, having a light grey colour and metallic lustre, and appearing compact on the fractured surface. 4 pts. platinum with 1 pt. molybdenum form a hard, brittle, bluish-grey alloy, having a granular fracture (Hjelm).—The alloy of 1 pt. *silver* and 2 pts. molybdenum is grey, granular, and brittle.

Molybde of Aluminium, $\text{Al}^{\circ}\text{Mo}$, is obtained by dissolving molybdic acid in hydrofluoric acid, evaporating to dryness, and fusing the residue with a mixture of 30 pts. cryolite, 30 pts. of a mixture of the chlorides of sodium and potassium in equivalent proportions, and 15 pts. aluminium, at a strong red heat. On treating the resulting regulus with soda-lye, there remains a crystalline powder coloured black by a film of metallic molybdenum, but assuming an iron-grey colour when treated with nitric acid, and appearing under the microscope to consist of rhombic prisms. It acquires a steel-blue tarnish when ignited in the air, and dissolves easily in hot nitric and hydrochloric acids. (Wöhler, Ann. Ch. Pharm. cxv. 102.)

MOLYBDENUM, BROMIDES OF. (Blomstrand, J. pr. Chem. lxxvii. 88; lxxxii. 433; Jahresb. 1859, p. 164; 1861, p. 239.) When bromine-vapour is passed over strongly heated molybdenum, an oxybromide is first formed, then a greyish-green sublimate of tribromide close to the heated part of the tube, the metal at the same time acquiring a yellowish-red colour and being at last completely converted into dibromide; between these two products there are also found isolated shining needles of the tetrabromide, of a pure black colour.

* "Est et molybdæna, quam alio loco galenam vocavimus, vana argenti plumbique communis." (Pliny.)

The *Dibromide* or *Molybdous bromide*, $\text{Mo}^{\text{II}}\text{Br}^2$, is produced, as just stated, by direct combination of its elements, also by heating the tribromide. It is a non-volatile, amorphous, reddish-yellow body, which is not perceptibly attacked by hydrochloric, nitric, or even boiling nitromuriatic acid, but dissolves easily and completely when heated with dilute caustic alkalis, forming a yellow solution containing molybdous oxybromide.

Concentrated solutions of caustic alkalis decompose the bromide completely, with precipitation of a black hydrated oxide.

The yellow solution above mentioned, when exposed to the air, gradually deposits small shining golden yellow crystals of a hydrated molybdous oxybromide, $\text{Mo}^{\text{II}}\text{Br}^2\text{O} \cdot 9\text{H}^2\text{O}$; but when neutralised with an oxygen-acid, it yields a dark yellow, flocculent or granular precipitate of the same oxybromide with a smaller quantity of water, $\text{Mo}^{\text{II}}\text{Br}^2\text{O} \cdot 0.3\text{H}^2\text{O}$. The oxybromide dissolves with yellow colour in alkalis and in the stronger oxygen-acids, and from the acid solutions thus obtained, the bromine is not precipitated by silver salts.—The solution of the oxybromide in dilute aqueous alkalis forms with *hydrobromic*, *hydrochloric*, or *hydriodic acid*, a yellow precipitate, insoluble in acids, but soluble in alkalis, and consisting of $\text{Mo}^{\text{II}}\text{Br}^2 \cdot 3\text{H}^2\text{O}$, $\text{Mo}^{\text{II}}\text{Br}^2\text{Cl}^2 \cdot 3\text{H}^2\text{O}$ or $\text{Mo}^{\text{II}}\text{Br}^2\text{I}^2 \cdot 3\text{H}^2\text{O}$.—Blomstrand regards all these compounds as containing the diatomic radicle, *bromomolybdenum*, MoBr^2 , e. g., the oxybromide, $(\text{MoBr}^2)^{\text{II}}\text{O}$, the chlorobromide, $(\text{MoBr}^2)^{\text{II}}\text{Cl}^2$, &c. (See page 1030.)

The *Tribromide*, $\text{Mo}^{\text{III}}\text{Br}^3$, or *Molybdoso-molybdic bromide*, $\text{MoBr}^2 \cdot \text{MoBr}^2$, is produced as above mentioned, by direct combination, or with greater facility by passing bromine-vapour over a heated mixture of molybdic oxide and charcoal. It is sometimes obtained in separate crystals, but more frequently in blackish-green masses consisting of delicate, capillary, interlaced needles. It is difficult to sublime, and at a bright red heat is resolved into the dibromide and free bromine. It is not even wetted by water, and not attacked by boiling hydrochloric acid or by cold dilute nitric acid. Dilute alkalis act upon it slowly, and at the boiling heat decompose it completely, with separation of black molybdic hydrate.

The *Tetrabromide* or *Molybdic bromide*, $\text{Mo}^{\text{IV}}\text{Br}^4$, formed also by direct combination (p. 1028), is fusible and volatile, forming a brown-red vapour; it deliquesces in the air to a black liquid; and forms with water a yellow-brown solution, from which alkalis throw down molybdic hydrate of a rusty yellow colour. It is easily resolved by heat into the dibromide and free bromine, the temperatures at which it is formed and decomposed being very close together.

The *hexabromide*, $\text{Mo}^{\text{VI}}\text{Br}^6$, has not been obtained, but the corresponding *oxybromide*, $\text{Mo}^{\text{VI}}\text{Br}^6\text{O}^3$, is produced by passing bromine-vapour over heated molybdic oxide, MoO^3 , or by heating molybdic trioxide with boric, or phosphoric anhydride, and fusing the pulverised mass with bromide of potassium, e. g.:

When quickly sublimed, it forms indistinct crystalline scales; but by slow sublimation it may be obtained in more distinctly developed crystalline plates of yellow-red colour and fatty lustre, which deliquesce in contact with the air, and form a colourless solution in water.

MOLYBDENUM, CHLORIDES OF. Molybdenum forms three chlorides, analogous to the bromides. The tri-chloride and tetrachloride were first prepared by Berzelius, who also obtained the dichloride in solution; these compounds have been more fully examined by Blomstrand, who has also obtained the anhydrous dichloride and several oxychlorides.

Dichloride or *Molybdous Chloride*, $\text{Mo}^{\text{II}}\text{Cl}^2$.—This compound is formed, together with the other chlorides, by passing chlorine-gas over heated molybdenum. It may be prepared, though not in a state of purity, by exposing the trichloride to a moderate heat in an atmosphere of carbonic anhydride, or other gas which does not act upon it, or by heating metallic molybdenum with calomel; also, though in very small quantity, by passing chlorine-gas largely diluted with carbonic anhydride over moderately heated molybdenum; it is likewise formed in small quantity, together with the tetrachloride, by passing chlorine over a heated mixture of molybdic oxide and charcoal when the temperature is very high. (Blomstrand.)

Molybdous chloride is obtained in solution, by saturating hydrochloric acid with molybdous hydrate. The dark-brown solution yields on evaporation a black mass which redissolves almost entirely in water, but on evaporation in vacuo, gives off hydrochloric acid and water, and is converted into a black pulverulent oxychloride. (Berzelius.)

The anhydrous dichloride is an amorphous powder of dull yellow colour, inclining to greenish from the presence of impurities. It behaves with *alkalis* like the dibromide, but dissolves easily and completely in *hydrochloric*, *hydrobromic*, and *hydriodic acids*. The alkaline solution when exposed to the air, deposits molybdous

oxychloride, $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{O}$, in combination with water, sometimes in very small crystals, but generally as an amorphous gummy precipitate. *Acids* (especially acetic acid)

added to the same solution, throw down the hydrated oxychloride, $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{O} \cdot 3\text{H}^{\circ}\text{O}$, in the form of light yellow flocks, which when recently precipitated, and washed with water, dissolves easily in the stronger acids. (Blomstrand.)

The hydrated oxychloride boiled with hydrobromic, hydriodic and hydrochloric acids, yields solutions which deposit compounds of exactly analogous constitution, having the oxygen replaced by an equivalent quantity of bromine, iodine or chlorine. With *hydrobromic acid*, the chlorobromide, $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 3\text{H}^{\circ}\text{O}$, is obtained, in thin reddish-yellow scales, insoluble in water, but soluble in alcohol; the alcoholic solution highly

concentrated at 100° , deposits short prismatic crystals containing $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 6\text{H}^{\circ}\text{O}$, easily soluble in water and forming a solution which, after a while, becomes turbid unless it contains a large quantity of free acid), and deposits a granular powder.

Similarly with *hydriodic acid*, the compound $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{I}^{\circ} \cdot 3\text{H}^{\circ}\text{O}$ is obtained, as a scaly crystalline substance, insoluble in water; also $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{I}^{\circ} \cdot 6\text{H}^{\circ}\text{O}$, which resembles the corresponding bromine-compound, but forms darker-coloured crystals. The cor-

responding *chlorine-compounds*, $\text{Mo}^{\circ}\text{Cl}^{\circ} \cdot 3\text{H}^{\circ}\text{O}$ and $\text{Mo}^{\circ}\text{Cl}^{\circ} \cdot 6\text{H}^{\circ}\text{O}$ (or $\text{MoCl}^{\circ} \cdot \text{H}^{\circ}\text{O}$ and

$\text{MoCl}^{\circ} \cdot 2\text{H}^{\circ}\text{O}$), are obtained in like manner, the former in thin scales insoluble in water, the latter in light yellow slender needles or prisms, which also dissolve in water, forming a solution which soon becomes turbid. The acid solutions of these compounds may be repeatedly evaporated to dryness, even in contact with the air without perceptible decomposition. The solid compounds heated in an atmosphere of carbonic anhydride, first give off nothing but water; but afterwards, if the heat be quickly raised, a certain quantity of acid is given off, so that the residue always contains more or less of the corresponding oxychloride, or even molybdous oxide, *e.g.*

The same decompositions take place, but to a greater extent, when these compounds are heated in contact with moist air.

The haloid molybdous compounds just described unite with the haloïd salts of potassium and ammonium, forming double salts having the composition $\text{Mo}^{\circ}\text{Cl}^{\circ} \cdot \text{KCl}$; $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 2\text{NH}^{\circ}\text{Br}$, $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 2\text{KBr}$, &c., which crystallise out almost completely from their acid solutions on cooling. These double salts vary in colour from shining straw-yellow (the chlorine-salts), to deep yellowish-red (the iodine-salts); they are of various, usually prismatic form; are decomposed by pure water, the alkali-metal salt dissolving, while the molybdous compound ($\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ}$, for example) separates in combination with $3\text{H}^{\circ}\text{O}$; but dissolve without decomposition in water containing free acid. *Alcohol* dissolves some of them ($\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 2\text{NH}^{\circ}\text{Br}$, for example) without decomposition, whereas from others (as $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 2\text{KBr}$) it dissolves the molybdous compound, and leaves the salt of the alkali-metal. *Nitrate of silver* added to the solutions of these double salts, throws down only half the amount of halogen contained in them (*e.g.* from $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{Br}^{\circ} \cdot 2\text{KBr}$, only the 4 at. bromine, and from $\text{Mo}^{\circ}\text{Cl}^{\circ} \cdot 2\text{KCl}$, or $\text{Mo}^{\circ}\text{Cl}^{\circ}\text{I}^{\circ} \cdot 2\text{KCl}$, only 4 at. chlorine); moreover their acid solutions are not decomposed by sulphydric acid, even after a day's contact (in the alkaline solutions it produces a slow decomposition), and they are not precipitated by ferro-cyanide of potassium. From these reactions, and from the composition of the double salts, Blomstrand infers that all these compounds contain the diatomic radicle, *chloromolybdenum* $\text{Mo}^{\circ}\text{Cl}^{\circ}$, that molybdous chloride is $(\text{Mo}^{\circ}\text{Cl}^{\circ})^{\circ}\text{Cl}^{\circ}$, the oxychloride $(\text{Mo}^{\circ}\text{Cl}^{\circ})^{\circ}\text{O}$, the chlorobromide $(\text{Mo}^{\circ}\text{Cl}^{\circ})^{\circ}\text{Br}^{\circ}$, &c.

Trichloride, $\text{Mo}^{\circ}\text{Cl}^{\circ}_3$ or *Molybdose, molybdic chloride*, $\text{MoCl}^{\circ}_3 \cdot \text{MoCl}^{\circ}$. This compound is obtained, though not in the pure state, by passing the vapour of molybdic chloride, MoCl°_3 , over heated molybdenum. Berzelius, who prepared it in this manner, but does not appear to have analysed it, regarded it as the dichloride; but according to Blomstrand's analysis, the compound thus obtained has nearly the composition MoCl°_3 . The trichloride is more easily obtained by passing hydrogen gas over the tetrachloride heated in a glass tube by a spirit-lamp; or better, by passing the vapour of the tetrachloride mixed with carbonic anhydride, through a tube, one part of which is very strongly heated; the trichloride then collects behind this portion, as a thick homo-

geneous crust (Blomstrand). It has a dark copper-red colour, and when heated to the melting point of glass, in a vessel which does not allow access of air, it volatilises and forms a confusedly crystalline, dark brick-red sublimate (Berzelius). It is insoluble in water, but colours that liquid reddish when suspended in it; insoluble also in dilute hydrochloric acid. When digested with potash it yields chloride of potassium and an insoluble blackish-brown hydrated oxide of molybdenum. (Berzelius.)

Tetrachloride or Molybdic chloride, $\text{Mo}^{\text{VI}}\text{Cl}_4$. This compound, discovered by Berzelius, is produced when chlorine gas, free from air, is passed over gently heated molybdenum. The metal then takes fire and burns on the surface for a few seconds; but this effect soon ceases and a dark red gas is formed, which condenses on the cold parts of the vessel in dark coloured metallic-shining crystals having very much the aspect of iodine. Blomstrand prepares it by the action of chlorine on strongly heated molybdic sulphide (the native sulphide). The crystals are very fusible (Berzelius), somewhat difficult of fusion (Blomstrand), and sublime at a moderate heat. When exposed to the air, they fume at the first instant, and then deliquesce, the original black colour of the liquid passing through blue-green, greenish-yellow, and dark red into yellow. When kept in a vessel containing air, they absorb oxygen and yield a sublimate consisting of an oxychloride.

Molybdic chloride when thrown into water, dissolves with such violence that the liquid effervesces and boils, as if a gas were given off, which however is not the case. A small quantity of the chloride drenched with a large quantity of water forms a solution which soon turns green or blue from the oxidising action of the air; a stronger solution is more permanent, and may be evaporated to dryness at a gentle heat without decomposition, the tetrachloride then remaining as a black mass. Molybdic chloride may also be obtained in solution by digesting the metal in hydrochloric acid, and adding nitric acid from time to time till the liquid acquires a red-brown colour, or by digesting molybdic anhydride and pulverised molybdenum (or metallic copper) in hydrochloric acid, till all the molybdic anhydride is dissolved and the liquid has become red. In all these solutions, ammonia forms a precipitate of molybdic hydrate.

Ammonio-molybdic chloride is obtained, according to Berzelius, by mixing a solution of molybdic chloride with ammonia, till the precipitate just begins to be permanent, and leaving the solution to evaporate, the double salt then separating in small brown crystals which decompose in contact with air.

A solution of molybdic chloride saturated with sal-ammoniac and left to evaporate over oil of vitriol, first deposits brown crystals of sal-ammoniac; and the mother-liquor ultimately yields green octahedrons of the double salt $3\text{MoCl}_4 \cdot 2\text{NH}_4\text{Cl} \cdot 6\text{H}_2\text{O}$, which soon deliquesce in moist air to a black liquid becoming reddish-yellow when diluted, and yielding with ammonia a yellowish-red precipitate of molybdic hydrate. (Blomstrand.)

MOLYBDENUM, CHLOROBROMIDES OF. This compound, $\text{Mo}^{\text{VI}}\text{BrCl}_3$, is obtained by the action of hydrochloric acid on molybdous oxybromide, and $\text{Mo}^{\text{VI}}\text{Cl}_2\text{Br}_2$ by that of hydrobromic acid on molybdous oxychloride. (Blomstrand, pp. 1029, 1030.)

MOLYBDENUM, DETECTION AND ESTIMATION OF. 1. *Blow-pipe reactions.*—Molybdic trioxide heated on charcoal in the outer flame is volatilised and forms a white crystalline sublimate on the charcoal; in the inner flame it may be reduced (even without carbonate of sodium) to metallic molybdenum, which is separated as a grey powder on levigating the charcoal. With borax, all the oxides of molybdenum give, in the outer flame, a bead which is yellow while hot, and colourless on cooling; in the inner flame, a dark brown bead, which is opaque if excess of molybdenum is present. By long continued heating, the molybdic oxide may be separated in dark brown flakes, floating in the clear yellow glass. With microcosmic salt in the outer flame, all oxides of molybdenum give a bead which is greenish while hot, and colourless on cooling; in the inner flame, a clear green bead from which molybdic oxide cannot be separated by continued heat.

2. *Reactions in Solution.*—a. Solutions of molybdous salts obtained by dissolving molybdous oxide in acids are opaque and black. They yield with sulphuric acid a brown-black precipitate, and with sulphate of ammonium a yellowish-brown precipitate of sulphide of molybdenum, easily soluble in sulphide of ammonium. Alkalis and alkaline carbonates produce a brownish-black precipitate of molybdous hydrate insoluble in excess alkali, slightly soluble in the neutral carbonates, easily soluble in acid carbonate of potassium or carbonate of ammonium. Ferrocyanide and ferricyanide of potassium form dark brown precipitates insoluble in excess. Phosphate of sodium forms a white precipitate.

β. Solutions of molybdic salts form a reddish-brown solution. When heated in

the air, they have a tendency to become blue by oxidation. In contact with metallic zinc, they first blacken and then yield a black precipitate of molybdous hydrate. Their reactions with alkalis, sulphydric acid, &c., are similar to those of the molybdous salts, excepting that the precipitates are lighter in colour.

γ. Molybdates are colourless unless they contain a coloured base. Solutions of the alkaline molybdates yield with acids a precipitate of molybdic acid, soluble in excess of the precipitant. They are coloured yellow by sulphydric acid, from formation of a sulphomolybdate of the alkali-metal R^2MoS_4 , and then yield with acids a brown precipitate of trisulphide of molybdenum. This is an extremely delicate test for molybdic acid. They form white precipitates with the salts of the earth-metals, and precipitates of various colours with salts of the heavy metals; e.g. white with lead and silver salts; yellow with ferric salts; and yellowish-white with mercurous salts.—Stannous chloride produces immediately a greenish-blue precipitate, soluble in hydrochloric acid, forming a green solution, which turns blue on the addition of a very small quantity of the tin-solution. Mercurous nitrate forms a yellowish-white precipitate, soluble in nitric acid, blackened by ammonia. When tribasic phosphoric acid, or a liquid containing it, is added to the solution of molybdate of ammonium, together with an excess of hydrochloric acid, the liquid turns yellow, and after a while deposits a yellow precipitate of molybdic acid combined with small quantities of phosphoric acid and ammonia. This precipitate is soluble in ammonia and likewise in excess of the phosphate. The reaction is therefore especially adapted for the detection of small quantities of phosphoric acid. The dibasic and monobasic phosphates do not produce the yellow precipitate. Arsenic acid gives a similar reaction.

3. *Quantitative Estimation, and Separation.* When molybdenum occurs in the form of trioxide or molybdic anhydride (MoO_3), the best mode of estimating it is to convert it into the di-oxide, MoO_2 , by ignition in an atmosphere of hydrogen. This oxide, which is not at all volatile, may then be weighed. When molybdic acid exists in solution in ammonia or in other acids, the solution must be carefully evaporated by dryness and the residue treated as above.

Molybdenum is separated from most metals by its solubility in sulphide of ammonium. The filtered solution containing sulphomolybdate of ammonium is then treated with an excess of very dilute nitric acid, to precipitate the trisulphide; the precipitate is collected on a weighed filter and its weight determined, after which a known quantity of it is ignited in an atmosphere of hydrogen, to convert it into the disulphide, MoS_2 , from the weight of which the amount of molybdenum is calculated.

From arsenic, molybdenum may be separated by converting the arsenic into arsenic acid, and precipitating it by a magnesium-salt (i. 367). Antimony may be separated from molybdenum by the same process which serves to separate it from arsenic and tin (i. 369), the alkaline molybdates, like the arsenates and stannates, being soluble in water. For the separation of molybdenum from tungsten, see TUNGSTEN.

Molybdic acid is separated from the earths, by fusing the compound with carbonate of sodium, and digesting the fused mass in water, which dissolves molybdate of sodium, and leaves the earth as carbonate.

From the fixed alkalis, molybdic acid may be separated by precipitation with mercurous nitrate. The precipitate is thoroughly washed with a dilute solution of the mercurous nitrate, then dried and ignited at a moderate heat in a stream of hydrogen, whereby it is reduced to molybdic oxide.

4. *Atomic Weight of Molybdenum.* Berzelius, in 1818 (Schw. J. xxii. 51), endeavoured to determine the atomic weight of this metal by the quantity of molybdate of lead, $PbMoO_4$, obtained by precipitation from a known weight of the nitrate; in this way he obtained for molybdenum the number 92, which however he regarded as only an approximation.

Svanberg and Struve (Ann. Ch. Pharm. lxxiii. 209), from an extensive series of experiments, considered that the most accurate results were obtained by roasting the disulphide, MoS_2 , in air. They found in ten experiments, that the artificially prepared disulphide lost by roasting, from 9.925 to 10.366 per cent. of its weight; whence, taking the atomic weight of sulphur as 32, they obtained, as a mean result, the number 92.14; but the results of the individual experiments (even excluding the three which differed most widely from the rest) varied from 80.88 to 97.15, so that no great dependence can be placed on the mean result.

Berlin, in 1860 (Ann. Ch. Pharm. lxxv. 372), analysed the ammonium-salt,

and found the quantity of molybdic anhydride, MoO_3 , left on igniting it, to vary in four experiments, only between 81.555 and 81.612: mean 81.581, whence he obtains for molybdenum the number 92, nearly the same as that found by Svanberg and Struve.

On the other hand, Dumas (Ann. Ch. Phys. [3] lx. 129), by reducing crystallised

molybdic anhydride in a current of hydrogen, obtained in six experiments, values of Mo between 95.2 and 96.2: mean 95.7; he regards 96 as the true atomic weight of molybdenum, which is the same as that originally found by Berzelius.

MOLYBDENUM, FLUORIDES OF. *a. Molybdous Fluoride.*—Molybdous oxide dissolves in hydrofluoric acid, forming a purple-red liquid which dries up at a gentle heat to a varnish of the same colour; this residue when more strongly heated becomes darker in colour, and partly insoluble in water.

Potassio-molybdous fluoride is precipitated in pale red flocks on mixing a solution of molybdous fluoride with fluoride of potassium. It is dissolved by water containing a little free acid, and separates, during evaporation or on cooling, as a dark rose-coloured powder, which becomes lighter when dry. The *ammonium-salt* is exactly similar; the *sodium-salt* is more soluble.

β. Molybdic Fluoride.—The solution of molybdic hydrate in aqueous hydrofluoric acid is red, unless the acid is in very large excess, in which case it is almost colourless. After gentle evaporation, whereby it is soon rendered blue if the acid is not in excess, it leaves a black crystalline residue (of molybdic fluoride?), which redissolves perfectly in water, forming a red solution; but if somewhat more strongly heated, loses acid, and when dissolved in water, leaves a residue of molybdic oxide. (Berzelius.)

Double salts of molybdic fluoride are obtained by mixing the solution just described with the fluorides of the alkali-metals. They are rusty yellow powders, somewhat soluble in water.

The blue oxide of molybdenum yields with hydrofluoric acid a deep blue solution which does not crystallise. (Berzelius.)

γ. Hexfluoride. Molybdic trioxide dissolves readily and abundantly in aqueous hydrofluoric acid. The colourless solution has a sour and disagreeable metallic taste, and yields, on evaporation, a yellowish syrup which exhibits no signs of crystallisation; assumes a greenish or bluish tint when heated, in consequence of minute organic particles falling into it; redissolves but imperfectly in water after evaporation to complete dryness; and leaves an insoluble compound of molybdic trioxide with a small proportion of hydrofluoric acid, or of molybdic trioxide with hexfluoride of molybdenum, which, though soluble to a certain extent in pure water, is precipitated from it by the first-mentioned acid solution.

Several combinations exist of hexfluoride of molybdenum with the more basic metallic fluorides; they are not, however, known in the free state, but only in combination with salts of molybdic acid: e. g., $K^2MoO^4.K^2MoF^6$. (Berzelius.)

MOLYBDENUM GLANCE. Native sulphide of molybdenum (p. 1043).

MOLYBDENUM, IODIDES OF. Molybdenum and iodine do not act on one another, even at a red heat. By dissolving molybdous hydrate in hydriodic acid, a solution of *molybdous iodide* is obtained resembling that of molybdous chloride (p. 1029).

Molybdic iodide is obtained in solution by saturating hydriodic acid with molybdic hydrate. The solution is red, and yields by evaporation in contact with the air, a crystallised salt, which is red by transmission, brown by reflected light. It decomposes at a high temperature, giving off hydriodic acid and leaving molybdic oxide. The residue left on spontaneous evaporation redissolves in water. (Berzelius.)

MOLYBDENUM, IODOBROMIDES and IODOCHLORIDES OF. Mo^2BrI^2 and Mo^2ClI^2 .—These compounds are obtained by the action of hydriodic acid on molybdous oxybromide and oxychloride respectively (pp. 1029, 1030).

MOLYBDENUM, NITRIDES and AMIDES OF. (Tuttle, Ann. Ch. Pharm., ci. 285. Uhlraub, Fort. Ann. ci. 606; Jahrb. 1867, p. 194.)—These compounds, which have not been very exactly investigated, are obtained by passing ammonia-gas over molybdic fluoride, or the chloride of molybdenum, at high temperatures. Tuttle, by heating molybdic chloride in ammonia-gas till the resulting chloride of ammonium was volatilised, obtained a black sintered mass containing 82.8 per cent. molybdenum, probably consisting of $2MoN.Mo^2H^2N^2$.

Uhlraub has also obtained compounds of similar constitution by the action of dry ammonia-gas on molybdic chloride. The action takes place even at ordinary temperatures, and is attended with sufficient evolution of heat to partially fuse the mass and drive off chloride of ammonium. On subsequently applying a gentle heat, the product becomes viscid, and soon solidifies to a black fused mass, exhibiting stellate groups of brownish crystals on the colder parts; when completely freed from sal-ammoniac by rapid washing with water, and then dried in a vacuum over oil of vitriol, it exhibited a composition expressible by the formula $Mo^2H^2N^2$ or $4MoN.Mo^2H^2N^2$. This compound burns brightly in oxygen-gas, with formation of water, and gives off ammonia when ignited in hydrogen gas, or fused with hydrate of potassium. A compound resembling the preceding in external appearance, but consisting of $8MoN.Mo^2H^2N^2$, was obtained

by heating molybdic chloride in ammonia-gas, the heat being at last raised to low redness. Molybdic chloride, gradually heated to redness in a stream of ammonia-gas, yielded, but not always, the compound $\text{Mo}^{\text{v}}\text{N}^{\text{v}}$, which resembled the two preceding in most respects, but had a greyer colour; sometimes, however, nitrides were obtained, intermediate in composition between $\text{Mo}^{\text{v}}\text{N}^{\text{v}}$ and $\text{Mo}^{\text{iv}}\text{N}^{\text{iv}}$. All these compounds, when heated to whiteness in ammonia-gas, yield metallic molybdenum.

Molybdous chloride treated with ammonia-gas yields the same compounds, together with another, which, according to Uhrlaub, is analogous in composition to some of the platinum-bases.

Nitrides and amides of molybdenum are likewise obtained by the action of ammonia-gas on molybdic anhydride. The reaction appears to be very complicated, the products MoN^{v} , $\text{MoH}^{\text{v}}\text{N}^{\text{v}}$, $\text{Mo}^{\text{iv}}\text{N}^{\text{iv}}$, and $\text{Mo}^{\text{v}}\text{N}^{\text{v}}$, being obtained in different proportions according to the temperature, and often uniting together to form compounds varying greatly in composition.

MOLYBDENUM, OXIDES OF. Molybdenum forms three oxides, having the following composition:

Protoxide or Molybdous oxide	MoO
Dioxide or Molybdic oxide	MoO^2
Trioxide or Molybdic anhydride	MoO^3

The first two are basylous and form salts with acids; the third also unites loosely with some of the stronger acids, but it is decidedly of a chlorous character, uniting readily with the more basylous metallic oxides, and forming definite crystallisable salts called Molybdates. There is also an oxide (or perhaps more than one) intermediate between the di- and tri-oxide, which may be regarded as a molybdic molybdate.

Protoxide or Molybdous oxide, MoO . This oxide is produced by bringing the di- or tri-oxide, in presence of one of the stronger acids, in contact with any of the metals which are capable of decomposing water. Thus, when zinc is immersed in a concentrated solution of an alkaline molybdate mixed with a quantity of hydrochloric acid sufficient to redissolve the molybdic acid which is at first thrown down, the liquid becomes first blue, then reddish-brown, and finally black, and contains chloride of zinc and molybdous chloride. To separate the molybdenum from the zinc, ammonia is then added to the liquid in quantity just sufficient to precipitate the molybdenum, as black molybdous hydrate, while the zinc remains in solution. The precipitate, however, carries down with it a certain quantity of zinc-oxide, from which it may be freed by washing with ammonia; but it is difficult in this way to obtain molybdous hydrate quite free from zinc. A better mode of preparation is to agitate the acidulated solution of the molybdate with an amalgam of potassium containing only a very small quantity of potassium, and precipitate the resulting solution of molybdous chloride with ammonia as before.

Anhydrous molybdous oxide may be obtained by drying the hydrate over oil of vitriol in a vacuum, and then igniting it out of contact with the air; or directly by digesting the fused or sublimed trioxide for a considerable time with hydrochloric acid and zinc.

Anhydrous molybdous oxide is perfectly black by ordinary daylight; but that prepared by the last method exhibits a dark brass-yellow colour, when exposed to the direct rays of the sun; it also exhibits the crystalline form of the trioxide from which it has been prepared, and oxidises in the air more rapidly than ~~that~~ which is obtained by igniting the hydrate. The anhydrous oxide, when heated nearly to redness, emits a vivid but momentary light, indicating its passage into another modification. It is insoluble in acids, but the hydrate dissolves slowly, forming the molybdous salts, the solutions of which are black or purple, and nearly opaque, except when largely diluted, in which case they are transparent, and have a greenish-brown colour; their taste is astringent but not metallic; when exposed to the air, they oxidise, but not so rapidly as the molybdic salts.

Dioxide or Molybdic Oxide, MoO^2 .—This oxide is obtained: 1. By igniting molybdic hydrate in a vacuum (Berzelius).—2. By exposing the trioxide in a stream of hydrogen to a heat not greater than that of an ordinary spirit-lamp (Svanberg). It is also said to be produced by igniting molybdate of ammonium in a close vessel, or by igniting a mixture of potassic or sodic molybdate with sal-ammoniac, and dissolving out the soluble chloride with water; but the oxide thus obtained appears to be contaminated with nitrate of molybdenum.

Molybdic oxide is red-brown. It is not attacked by aqueous hydrofluoric or hydrochloric acid, or by hydrochloric acid gas at a red heat. Sulphuric acid or solution of acid tartrate of potassium takes up only traces of it, even on continued digestion, and the residue left after decanting the liquid is not attacked by fresh quantities of sulphuric acid or solution of cream of tartar. Molybdic oxide is further

oxidised by ignition in the air, or by treatment with nitric acid. Caustic potash-solution neither oxidises nor dissolves it.

Molybdic hydrate is obtained by precipitating a solution of molybdic chloride or other molybdic salt with ammonia, which must be added in excess, as otherwise a soluble basic salt will be formed, especially with the chloride. The hydrate itself is also somewhat soluble in pure water, so that, in very dilute solutions, ammonia does not form any precipitate until sal-ammoniac is added. For the same reason, the washing must not be carried too far, and is best finished with water containing alcohol. The washed hydrate may be pressed between paper and dried in a vacuum. It has a rusty brown colour, just like that of ferric hydrate precipitated by ammonia. When exposed in the moist state to the air on filtering paper, it acquires a darker colour and shining surface, and begins to deliquesce, passing into a higher and much more soluble oxide. It dissolves, as already observed, in a large quantity of water, forming a dark red solution, which gelatinises when kept for three or four weeks in a closed vessel, reddens litmus, a property likewise retained by the hydrate precipitated from it by sal-ammoniac, and has a somewhat astringent taste, with metallic after-taste. This solution, when left to evaporate spontaneously, first gelatinises and then dries up to a dark brown, nearly black mass, green and blue on the edges, which is no longer soluble in water. The hydrate is insoluble in caustic potash, but dissolves in aqueous neutral carbonate of potassium, and more easily in the acid carbonate, from which solution it is partially precipitated on boiling. It dissolves also in carbonate of ammonium, and is completely precipitated therefrom by boiling; the precipitate is denser and of a lighter yellow colour than that obtained with caustic ammonia, but dissolves, like the latter, when washed with water. A solution of molybdic oxide in an alkaline carbonate is converted by atmospheric oxidation into a molybdate of the alkali-metal.

Molybdic hydrate dissolves in acids, forming the molybdic salts. These salts may also be obtained by digesting an excess of metallic molybdenum with the acid in which it is to be dissolved, and adding nitric acid drop by drop till the other acid is saturated with molybdic oxide; or by digesting an excess of molybdenum with molybdic anhydride, and the acid which is required to dissolve the resulting molybdic oxide—hydrochloric acid, for example—till the blue colour first produced changes to reddish-brown; or lastly, by digesting molybdic anhydride with copper and an acid, which in that case dissolves cupric and molybdic oxides together. The molybdic salts, in the anhydrous state, are almost black, but when hydrated they are red, and yield reddish-brown solutions in water. They have a rough, somewhat astringent and subsequently metallic taste. Their solutions when heated in contact with the air, have a tendency to become blue by oxidation. [For their behaviour with reagents, see p. 1039.]

The oxides intermediate between the di- and tri-oxides will be described as molybdic molybdates (p. 1039).

Trioxide. *Molybdic Anhydride, Anhydrous Molybdic acid, MoO₃.*—This oxide occurs native, as molybdic ochre or molybdin, forming an earthy coating on the native sulphide, sometimes also independently; at Altenberg in Saxony it occurs in rhombic prisms of 136° 48' (Breithaupt, *Jahresb.* 1858, p. 683). It may be formed artificially by exposing molybdenum or its lower oxides, or molybdic sulphide, to long-continued heat in contact with the air, by fusing the same substances with nitre, or by heating the metal or its oxides in an atmosphere of aqueous vapour, or with hydrate of potassium.

Preparation. *a. From Molybdic Sulphide.*—The precipitated sulphide, or the native mineral finely pulverised, is roasted, with continued stirring, in an open crucible placed in a slanting position, so that the air may easily play upon its surface. The native sulphide, however, generally contains alumina, oxide of copper, and phosphoric acid, the separation of which from the product is very troublesome. Hence it is better to heat the mineral in lumps in an open glass tube, through which a stream of air is drawn by an aspirator; the trioxide then sublimes in crystals in a state of perfect purity. (Wöhler, *Ann. Ch. Pharm.* c. 376.)

b. From native Molybdate of lead.—The mineral finely pounded and freed from carbonates of zinc, iron, and calcium, by digestion in dilute hydrochloric acid, and thoroughly washed by decantation, is heated with 1½ pt. strong sulphuric acid, with constant stirring, till the sulphuric acid begins to evaporate. It is then allowed to cool, a considerable quantity of water is added, and the insoluble sulphate of lead is filtered off. The filtrate is mixed with nitric acid and evaporated, with constant stirring, in a porcelain basin, till the acid begins to evaporate; the molybdic anhydride then separates as a white powder, which may be freed from phosphoric acid by washing with water, mixed at the last with a few drops of nitric acid.—Or the mineral, after treatment with dilute hydrochloric acid, may be evaporated to dryness with strong hydrochloric acid, the dry residue (containing oxychloride of lead and molybdic anhydride) exhausted

with ammonia; the ammoniacal solution crystallised, or evaporated as before with nitric acid; and the residue treated with water. Or again, the mineral is fused with its own weight of calcined cream of tartar; the fused mass is exhausted with water; the aqueous solution evaporated to dryness, after saturation with nitric acid; and the nitrate of potassium is dissolved out of the residue with water: trioxide of molybdenum then remains behind.

Properties.—Trioxide of molybdenum, as usually prepared, forms a white, light, porous mass, which when thrown into water, separates into small thin scales having a silky lustre and glistening in sunshine. Specific gravity = 3.49. At a red heat it melts to a dark yellow liquid, which on cooling forms a straw-yellow mass, breaking up into crystalline scales. By slow cooling of the melted mass, slender needles are obtained belonging to the trimetric system and exhibiting the faces ∞P_{∞} , ∞P_2 , $\frac{2}{3} P_{\infty}$ &c. (referred to the prism ∞P , observed by Breithaupt on molybden). Ratio of secondary axes to principal axis = 1 : 0.3872 : 0.4792 (Nordenskiöld, Pogg. Ann. cxii. 160). In close vessels it bears a strong red heat without volatilising; but in open vessels or in a current of air, it sublimes at its melting point in colourless laminae.

Decompositions.—1. Molybdic trioxide is reduced:—1. To the metallic state by ignition with potassium or sodium (with vivid incandescence) or with charcoal; also when strongly heated in a stream of hydrogen.—2. To molybdous oxide, by digestion with hydrochloric acid and amalgam of potassium, or zinc, or other metal capable of decomposing water.—3. To molybdic oxide, by ignition in combination with ammonia, or by digestion with hydrochloric acid and molybdenum or copper; also, according to Buff (Ann. Ch. Pharm. cx. 257), by subjecting it in the fused state to the action of the electric current; the molybdic oxide thus separated unites with the excess of trioxide, forming the compound $MoO_3 \cdot 2MoO_3$ or Mo_3O_9 , which separates in crystalline laminae and gradually forms a conducting communication between the poles.—4. To the state of blue oxide, by a small quantity of sulphydric acid, in presence of water, or on exposure to heat, with separation of sulphur; by sulphurous acid, with production of sulphuric acid; by aqueous hydriodic acid, with separation of free iodine, and formation of a liquid which at first is green, but afterwards blue; by boiling hydrochloric acid, with disengagement of chlorine; by nitric oxide in presence of water, with formation of nitrous acid (Kastner, Kastn. Arch. xxvi. 465); by stannous chloride, with formation of stannic chloride; also by digestion with water and metallic molybdenum.—5. To sulphide of molybdenum, by sulphydric acid in excess, in presence of water, or when aided by heat. Molybdic trioxide is not affected by fusion with metallic molybdenum. (Berzelius.)

Combinations. 1. With Water.—Molybdic trioxide is but slightly hygroscopic. It dissolves, according to Bucholz, in 500 parts of cold water, and in a much smaller quantity at a higher temperature: according to Hatchett, it requires 960 parts of hot water. The solution has a faint metallic taste, reddens litmus-paper, yields a red precipitate with ferrocyanide of potassium, but not till one of the stronger acids is added. Graham (Chem. Soc. J. xvii. 326), by dialysing a solution of sodic molybdate mixed with a large excess of hydrochloric acid, has obtained a solution of molybdic acid (containing about 60 per cent. of the quantity present in the original solution), having a yellow colour, astringent to the taste, acid to test-paper, and capable of decomposing carbonates with effervescence. Evaporated to dryness at 100°, it leaves molybdic trioxide in scales like gum or gelatin, and still soluble in water. It does not appear possible to obtain molybdic acid in the solid state.

2. With Acids. The affinity of molybdic acid for other acids is very feeble. After ignition, it is but slightly soluble in a boiling aqueous solution of cream of tartar; before ignition, however, it dissolves in some of the stronger acids, e.g. in boric, phosphoric, sulphuric, nitric, and hydrochloric acids, forming compounds which may be called permolybdic salts. The solutions thus obtained are sometimes colourless, sometimes yellow or brownish. By metallic zinc or tin, they are first turned blue, then green, and lastly black, molybdous oxide being precipitated; by digestion with copper, they become dark red. Stannous chloride produces a greenish-blue precipitate, which dissolves in hydrochloric acid, forming a green solution. Sulphydric acid, in small quantities, colours them blue; in larger quantities it produces a blackish-brown precipitate (a mixture of disulphide of molybdenum with sulphur, according to Berzelius). Sulphide of ammonium behaves in a similar manner to sulphydric acid (Bucholz, Berzelius). Ferrocyanide of potassium produces a dense, reddish-brown precipitate, soluble in excess of the reagent, and also in ammonia (Berzelius). Ferrocyanide of potassium gives a somewhat lighter coloured precipitate, which is likewise soluble in ammonia (H. Rose). Tincture of galls throws down a green precipitate. (Smithson.)

Permolybdic Borate. Molybdic trioxide dissolves in boiling aqueous boric acid, and the filtered solution yields by evaporation colourless crystals, decomposable by alcohol into a yellow powder and boric acid. (Berzelius.)

Permolybdic Nitrate. The solution of molybdic trioxide in nitric acid is reddish-brown, has a feebly acid and subsequently bitter, metallic, astringent taste, and gives off nitric acid when evaporated.

Permolybdic Phosphate or Phosphomolybdic Acid. Molybdic trioxide digested while still moist with a small quantity of aqueous phosphoric acid, yields a lemon-yellow salt insoluble in water (Berzelius). With a larger proportion of phosphoric acid, this yellow salt dissolves on the application of heat, forming a colourless liquid, which yields by evaporation a tenacious, uncrystallisable, transparent mass, having a very rough taste, and very soluble in water and in alcohol. The alcoholic solution is yellow, but turns blue on evaporation, and leaves a brown, opaque residue, which redissolves in water, forming a blue solution. (Berzelius; see also Svanberg and Struve, Ann. Ch. Pharm. lxxviii. 209, 293.)

The yellow precipitate formed on adding molybdate of ammonium to the solution of a tribasic phosphate (p. 1032) appears to vary in composition according to the circumstances of its formation; at all events the formulae (all very complicated) assigned to it by different chemists do not agree with one another (see Nutting, Jahresb. 1855, p. 274.—Seligsohn, *ibid.* 1856, p. 375.—Eggertz, *ibid.* 1860, p. 620).—[For the modes of applying phosphomolybdic as a test for the alkaloids, see i. 127.]

Permolybdic Sulphate. By boiling dilute sulphuric acid with an excess of molybdic trioxide, a turbid, milky liquid is obtained, which gelatinises on cooling, and deposits pale yellow flakes of a basic compound, sparingly soluble in water but not in alcohol, though the latter colours it green. (Berzelius.)

A solution of molybdic trioxide (not in excess) in dilute sulphuric acid has a light yellow colour, and dries up to a lemon-yellow crystalline mass, which deliquesces in the air, but is only partially soluble in water (Berzelius). According to Anderson (Berz. Jahresb. xxiii. 161), the solution of molybdic acid in sulphuric acid does not yield crystals on evaporation; but when molybdate of barium is decomposed by excess of dilute sulphuric acid, and the clear solution evaporated over oil of vitriol, crystals are obtained.

Permolybdic Tartrate. The solution of molybdic trioxide in aqueous tartaric acid, yields by evaporation a blue non-crystalline mass, perfectly soluble in water and in alcohol. A boiling solution of acid tartrate of potassium easily dissolves molybdic trioxide, even after ignition. The solution dries up to a gunny mass of *potassio-permolybdic tartrate*. (Berzelius.)

3. With Bases, forming the MOLYBDATES. Molybdic trioxide exhibits with most metallic oxides the characters of an anhydrous acid, or anhydride, forming neutral molybdates containing $R^2O.MoO^3$ or R^2MoO^4 ; acid and double molybdates, which may be represented by the general formula $R^mMo^mO^{4m}$, the molecule R^m being made up of two or more metals, including hydrogen; and anhydro-molybdates, expressible by the general formula $R^mMo^mO^{4m}.mMoO^3$, the letters m and n representing whole numbers. The neutral molybdates of the alkali-metals are easily soluble in water, and are obtained by digesting molybdic anhydride with the aqueous alkalis or alkaline carbonates. They are decomposed by the stronger acids, with precipitation either of a less soluble acid salt, or of molybdic anhydride. Their behaviour with other reagents has been already described (p. 1032). The molybdates of the other metals are insoluble, and are obtained by precipitation. They are colourless unless they contain a coloured base.

Molybdate of Aluminium. White precipitate, insoluble in water.

Molybdates of Ammonium. The neutral salt, $(NH_4)^2MoO^4$, is obtained by treating molybdic anhydride in excess with strong aqueous ammonia in a closed vessel, precipitating the solution with alcohol, and drying over quicklime.

Acid salts.—These are obtained by evaporating a solution of molybdic anhydride in excess of ammonia. If the evaporation takes place quickly, a crystalline powder is precipitated, which, according to Svanberg and Struve, is an anhydro-molybdate, $(NH_4)^2O.2MoO^3$ or $(NH_4)^2MoO^4.MoO^3$. It is probable, however, that the salt thus prepared contains 1 at. water, $[(NH_4)^2O.2MoO^3.H^2O]$, in which case it may be regarded as an ammonio-hydric molybdate, $\frac{NH_4}{H} \left\{ MoO^4 \right\}$. A salt having this composition is in

fact described by v. Rath (Pogg. Ann. cx. 18) as crystallising in monoclinic prisms, $\infty P : \infty P_3 : [\infty P \infty] : \infty P_\infty - P + 2P$, and having the ratio of the axes $a : b : c = 0.6297 : 1 : 0.2936$; the angle of the inclined axes = $91^\circ 12'$; and perfectly cleavable parallel to $[\infty P \infty]$.

c. A tetrammonio-hexahydric-molybdate, $\frac{(NH_4)^6}{H^6} \left\{ Mo^3O^9 \right\}$, separates from a solution of molybdic anhydride in ammonia, when concentrated to the crystallising point or left to evaporate in the air, in large transparent six-sided prisms. (Svanberg and Struve.) When a solution of this salt is boiled with aluminate, chromic, ferric or manganic

MOLYBDENUM : OXIDES.

and then evaporated to the crystallizing point, double salts are obtained, the composition of which may be represented by that of the aluminic salt, viz.

crystallises in small, white, shining, quadratic plates, less soluble in water than the corresponding potassium-salt (which dissolves in 10.67 pts. water at 17°). The crystals give off 2 at. water when exposed to the air, and 23 atoms more (the remaining water of crystallisation) between 100° and 120°, without losing their lustre; the remaining 3 at. (which are basic) at a higher temperature only; when strongly heated, they yield a yellowish residue of alumina and molybdic anhydride, retaining the form of the original crystals.

The *ammonio-chromic salt* crystallises in small rose-red quadratic plates, which give off 5 at. water at 100° and 2 at. more at 120°, and when heated to redness, leave a mixture of chromic oxide and molybdic anhydride; the *ammonio-ferric salt* forms yellowish-white crystals of the same form, but difficult to obtain pure in any considerable quantity.

The *ammonio-manganic salt*, $5[(\text{NH})^{10}_2\text{O}.2\text{MoO}^3] + \text{Mn}^{10}\text{O}^3.6\text{MoO}^3 + 12\text{H}^2\text{O}$, or $(\text{NH})^{10}_2\text{O}. \text{Mo}^{10}\text{O}^3.2\text{H}^2\text{O}$, is isomorphous with the corresponding potassium-salt (p. 1049);

dissolves in 101.7 pts. water at 17°; is permanent in the air; and gives off three-fourths of its total quantity of water at 100°. (Struve.)

Molybdates of Barium. The *monobarytic salt*, $\text{Ba}^{10}\text{MoO}^4$, is precipitated as a sparingly soluble crystalline powder, on adding chloride of barium to a solution of molybdic acid in excess of ammonia. (Svanberg and Struve.)

Schultze by fusing together 2 pts. molybdate of sodium, 6 pts. chloride of barium, and 2 pts. chloride of sodium, obtained the same salt in distinct quadratic pyramids, with 4 pts. sodic chloride it was obtained as a crystalline powder.

The salts $\text{Ba}^{10}\text{H}^{10}\text{Mo}^{10}\text{O}^{10}.3\text{H}^2\text{O}$ and $\text{Ba}^{10}\text{H}^{10}\text{Mo}^{10}\text{O}^{10}.3\text{H}^2\text{O}$ are obtained by precipitating the corresponding potassium- and ammonium-salts with chloride of barium; and by decomposing monobarytic molybdate with dilute nitric acid, an anhydrous salt is formed containing $\text{Ba}^{10}\text{MoO}^4.8\text{MoO}^3.4\text{H}^2\text{O}$, crystallised in small six-sided prisms, fusible and insoluble in water. (Svanberg and Struve.)

Molybdate of Cadmium, $\text{Cd}^{10}\text{MoO}^4$, if obtained in shining yellow laminae by melting together 2 pts. molybdate of sodium, 7 pts. chloride of cadmium, and 3 pts. common salt. (Schultze.)

Molybdate of Calcium, $\text{Ca}^{10}\text{MoO}^4$, is obtained by fusing together 2 pts. molybdate of sodium, 8 pts. chloride of calcium, and 4 pts. common salt, in white, well-developed quadratic pyramids. (Schultze.)

Cerous Molybdate is obtained by precipitation, in white flakes insoluble in water, but soluble in several acids. (Berzelius.)

Molybdates of Chromium. Ammonio- and potassio-chromic molybdates are obtained, as above described, by dissolving chromic hydrate in the acid molybdates of ammonium and potassium.

Molybdate of Cobalt is obtained in greyish-green indistinct crystals, by fusing 1 pt. molybdate of sodium with 2 pts. chloride of cobalt and 2 pts. common salt. (Schultze.)

Cupric Molybdate. Yellowish-green precipitate sparingly soluble in water, decomposed by acids and by alkalis (Berzelius). Acid molybdate of ammonium added to a boiling solution of cupric sulphate throws down a heavy green amorphous powder, consisting of a basic cupric molybdate, $4\text{Cu}^{10}\text{O}.3\text{MoO}^3.5\text{H}^2\text{O}$, or $3\text{Cu}^{10}\text{MoO}^4.\text{Cu}^{10}\text{H}^{10}\text{O}^3.4\text{H}^2\text{O}$. By adding molybdate of ammonium in excess to a cold solution of cupric sulphate, an *ammonio-cupric salt* is formed consisting of $\text{Cu}^{10}(\text{NH})^{10}_2\text{Mo}^{10}\text{O}^3.3\text{MoO}^3.9\text{H}^2\text{O}$ or $[\text{Cu}^{10}(\text{NH})^{10}_2\text{H}^{10}\text{Mo}^{10}\text{O}^3.6\text{H}^2\text{O}]$. It is a white-blue crystalline powder which gives off 4 at. water at 100° and 4 at. more at 200°. (Struve.)

Molybdate of Iron. Monoferrous molybdate, $\text{Fe}^{10}\text{MoO}^4$, is obtained in dark brown monoclinic prisms by fusing 1 pt. molybdate of sodium with 3 pts. ferrous chloride and 2 pts. common salt (Schultze). Ferrous sulphate added to a solution of potassio molybdate reduces the molybdic acid to a lower stage of oxidation; but if chlorine be passed through the solution at the same time, a bulky precipitate is formed, which, when dried in the air, forms a light yellow powder consisting of $\text{Fe}^{10}\text{O}^3.5\text{MoO}^3.16\text{H}^2\text{O}$ (Struve). A solution of acid molybdate of ammonium mixed with a neutral solution of ferric chloride immediately produces a bulky sulphur-yellow precipitate, which when dried contains $\text{Fe}^{10}\text{O}^3.4\text{MoO}^3.7\text{H}^2\text{O}$. (Steinacker, Jahresb. 1861, p. 238.)

A mineral from Nevada city in California, described by Owen (Jahresb. 1852, p. 887) as a ferric molybdate, is, according to Genth (Sill. Am. J. [2] xxviii. 241), very

MOLYBDATES.

variable in composition, and appears to be merely a mixture of molybdate, molybdenite and brown hematite.

Ammonio-ferric and *Potassio-ferric* molybdates are obtained in the manner already mentioned (p. 1037).

Molybdate of Lead. $\text{PbO} \cdot \text{MoO}_3 = \text{Pb}^{\text{II}} \cdot \text{MoO}_4$. This salt occurs native as *Wulfenite* or *Yellow Lead ore* (*Gabblerz*) in modified square tables and octahedrons belonging to the dimetric system, the most frequent forms being P and P. oP. Length of principal axis = 1.574. Angle $\angle \text{P}$ in the terminal edges = $99^\circ 40'$; in the lateral edges = $131^\circ 35'$. Cleavage indistinct parallel to P. It occurs also granularly massive, coarse or fine, firmly coherent. Hardness = 2.75 to 3. Specific gravity = 6.3 to 6.9. Lustre resinous or adamantine. Colour was yellow passing into orange-yellow, also siskin- and olive-green, yellowish-grey, greyish-white and brown. Streak white. Sub-transparent to subtranslucent. Fracture subconchoidal. Brittle. When heated, it decrepitates strongly, and assumes a darker colour, disappearing however on cooling, and fuses to a yellow mass. When fused on charcoal before the blowpipe, it sinks into the charcoal, leaving globules of lead, the charcoal at the same time becoming impregnated with molybdenum and molybdiide of lead. It dissolves easily in borax and in microcosmic salt, exhibiting the reactions of molybdenum already mentioned (p. 1032). It dissolves in hot nitric acid, with separation of yellowish-white permolybdic nitrate, (p. 1037). Strong hydrochloric acid dissolves it, forming a green solution, together with chloride of lead, which separates more completely on addition of alcohol. It dissolves also in caustic potash.

Molybdate of lead occurs, with other lead ores, in veins of limestone, at Schwarzenbach, Bleiberg, and Windisch-Kappel, in Carinthia; it is also found at Retzbanya, in Hungary, and at Moldawa in the Bannat, where the crystals are red, and bear considerable resemblance to chromate of lead; in small quantities also at the Southampton Lead mine, Massachusetts, and in fine reddish-orange crystals, containing a trace of chromic acid, at Wheatley's lead mine near Phoenixville, Pennsylvania. The specimens from these several localities are nearly pure, the proportion of molybdic anhydride found by analysis varying from 37.65 to 40.5 per cent., and that of lead-oxide from 59.0 to 62.3 per cent., while the formula $\text{PbO} \cdot \text{MoO}_3$ requires 38.5 per cent. MoO_3 and 61.5 PbO. The Bleiberg mineral contains a small quantity of vanadium.

Molybdate of lead is formed artificially by precipitating nitrate of lead with neutral molybdate of ammonium; also, according to Schulze, by fusing 2 pts. molybdate of sodium with 6 pts. chloride of lead and 4 pts. common salt. As thus prepared, it forms crystals, white when pure, yellow if they contain a little phosphoric acid. Mixtures, in varying proportions, of molybdate of sodium, chromate of potassium, chloride of lead, and common salt, yield crystallised salts, which, when they contain not more than 42 per cent. chromate of lead, are quadratic like those of pure molybdate of lead, but with a deep red colour; with from 42 to 90 per cent. chromate of lead, they are monoclinic and yellow.

A molybdate of lead from Pampuluna, in South America, was found by Boussingault (*Ann. Ch. Phys.* [3] xlv. 325) to contain 78.8 per cent. $\text{PbO} \cdot 10.0 \text{ MoO}_3$, 2.9 CO_2 , 1.3 HCl, 1.3 P_2O_5 , 1.2 Cr_2O_3 , 1.7 FeO , 2.2 Al_2O_3 and 3.7 quartz (= 98.1); he regards it as a basic salt, $3\text{PbO} \cdot \text{MoO}_3$ or $\text{Pb}^{\text{II}} \cdot \text{MoO}_4 \cdot 2\text{Pb}^{\text{II}}\text{O}$.

Molybdate of Magnesium, $\text{Mg}^{\text{II}} \cdot \text{MoO}_4 \cdot 5\text{H}_2\text{O}$, is obtained in distinct crystals by boiling molybdic acid and magnesia alba with water, and evaporating the filtrate; it gives off 3 at. water at 100° . (Struve.)

Molybdate of Manganese is obtained as a heavy white, crystalline powder, containing $\text{Mn}^{\text{II}} \cdot \text{MoO}_4 \cdot \text{H}_2\text{O}$, by treating carbonate of manganese with trimolybdate of potassium or sodium; it gives off its water above 100° , dissolves sparingly in boiling water, and when boiled for some time with the acid molybdate of potassium or sodium, yields double salts (Struve). Schultze, by fusing 1 pt. molybdate of sodium with 3 pts. manganous chloride, and 2 pts. common salt, obtained the anhydrous salt $\text{Mn}^{\text{II}} \cdot \text{MoO}_4$, in large dingy yellow crystals having the aspect of bitter-salt and appearing under the microscope as small monoclinic (?) tablets. Together with this salt there are often formed large red-brown laminae of indeterminate form.

Ammonio- and potassio-manganic molybdates are prepared by boiling the acid molybdates of ammonium and potassium with manganic hydrate (pp. 1027, 1040).

Molybdates of Mercury. On adding mercurous nitrate to a solution of trimolybdate of potassium, a yellowish-white flocculent precipitate is formed, which, if immediately collected on a filter, and washed till the wash-water leaves no residue on evaporation and ignition, consists of *mercurous dimolybdate* or *anhydro-molybdate*, $\text{Hg}^{\text{I}} \cdot 2\text{MoO}_3$ or $\text{Hg}^{\text{I}} \cdot \text{MoO}_4 \cdot \text{MoO}_3$. It is yellowish-white and non-crystalline, but is converted by prolonged washing, or more quickly by boiling in the mother-liquor, into

golden-yellow needle-shaped crystals of *neutral mercurous molybdate*, Hg^2MoO_4 . (Struve.)

Molybdates of Molybdenum. There are several oxides of molybdenum, intermediate in composition between the di- and tri-oxides, which are probably molybdates containing molybdenum as their base. When a solution of molybdate of ammonium is mixed with a solution of molybdic chloride, a blue precipitate is formed having the composition of a molybdic molybdate, $\text{Mo}^{\text{O}^2}\cdot 4\text{Mo}^{\text{O}^3}\text{O}^3$ or Mo^{O^4} . The precipitate thus formed is, however, a hydrate, which becomes nearly black when ignited. The same blue hydrate is formed by the oxidation of molybdic, or the reduction of permolybdic salts (pp. 1035, 1036). It is very sparingly soluble in sal-ammoniac, somewhat more in water, slightly also in alcohol. The aqueous solution has a dark blue colour, remains unaltered at ordinary temperatures, but bleaches more and more by oxidation when evaporated by heat. A concentrated solution is resolved by alkalis immediately, a dilute solution on warming, into molybdic hydrate and molybdic anhydride.

Another molybdic molybdate, supposed by Berzelius to have the composition $\text{MoO}^2\cdot 2\text{MoO}^3 = \text{Mo}^{\text{O}^4}$, is formed when a mixture of the preceding compound with molybdic chloride is precipitated by ammonia, also when the blue oxide is digested with pulverised molybdenum, or when 2 pts. of the pulverised metal and 1 pt. molybdic trioxide are digested with a large quantity of water in a closed vessel, the colour of the liquid then changing from blue to green. From these solutions pulverised sal-ammoniac throws down the compound as an olive-green precipitate, which redissolves when washed with water. From the product obtained by the first method, water dissolves, first the compound $\text{MoO}^2\cdot 4\text{MoO}^3$, and afterwards molybdic hydrate. (Berzelius.)

Molybdate of Nickel forms as a light apple-green precipitate. Schultze, by fusing molybdate of sodium with chloride of nickel, obtained it in leaf-green monoclinic prisms, together with lemon-yellow crystals of indeterminate form.

Molybdates of Potassium.—A. The *neutral* or *monomolybdate*, $\text{K}^2\text{O}\cdot\text{MoO}^3$, or K^2MoO^4 , is obtained by agitating the trimolybdate with alcoholic potash; it then separates as an oily mass, which, when dried over lime and oil of vitriol, crystallises in four-sided prisms containing $2\text{K}^2\text{MoO}^4\cdot\text{H}^2\text{O}$. It is also produced by mixing a solution of molybdate of ammonium with excess of carbonate of potassium, and evaporating to a syrup.

B. When a solution of molybdic acid in carbonate of potassium is mixed with strong nitric or hydrochloric acid, till a slight permanent precipitate appears, the liquid, after a while, yields crystals of a salt containing $4\text{K}^2\text{O}\cdot 9\text{MoO}^3\cdot 6\text{H}^2\text{O}$, or $(\text{K}^2\text{H}^{10})\text{Mo}^{\text{O}^6}\cdot\text{H}^2\text{O}$; and this salt is decomposed by water into the monomolybdate, which dissolves readily, and the trimolybdate, which is sparingly soluble:

The *trimolybdate* dissolves easily in boiling water, and separates as a milky-white precipitate when the solution is quickly cooled; but by slow cooling it is obtained in beautiful silky needles containing $\text{K}^2\text{O}\cdot 3\text{MoO}^3\cdot 3\text{H}^2\text{O}$, or $(\text{K}^2\text{H}^4)\text{Mo}^{\text{O}^4}\cdot\text{H}^2\text{O}$.

Nitric acid added in excess to a solution of molybdic acid in carbonate of potassium, throws down a white precipitate, consisting sometimes of $\text{K}^2\text{O}\cdot 4\text{MoO}^3$, sometimes of $\text{K}^2\text{O}\cdot 5\text{MoO}^3$, both anhydrous. (Svanberg and Struve.)

Potassio-aluminic Molybdate, $\text{Al}^{\text{III}} \left. \begin{matrix} \text{K}^3 \\ \text{H}^6 \end{matrix} \right\} \text{Mo}^{\text{O}^2}\cdot 7\text{H}^2\text{O}$.—This salt, analogous in composition to the ammonio-aluminic molybdate already described (p. 1037), is prepared

either by prolonged boiling of a solution of trimolybdate of potassium with aluminic hydrate; or by precipitating a solution of alum with a neutral molybdate, that of magnesium, for example, and boiling the washed precipitate, consisting of aluminic hydrate, sulphate, and molybdate (mixed perhaps with a little potash), with a solution of potassic trimolybdate, and evaporating the filtrate to the crystallising point. It crystallises in groups of small white square tablets, soluble in 40·7 pts. water at 17°; is permanent in air at ordinary temperatures; gives off 6 at. water at 100°; melts when more strongly heated, and solidifies on cooling to a yellowish crystalline mass, very slowly soluble in water and even in acids. (Struve.)

The *potassio-chromic salt* of similar constitution, crystallises in rose-coloured tablets soluble in 38·51 per cent. water at 17°, permanent in the air, giving off 10 at. water at 100°, and behaving at higher temperatures like the aluminic salt. (Struve.)

The *potassio-ferric salt* forms yellowish-white crystals of the same form as the preceding salts; difficult to obtain in any considerable quantity. (Struve.)

The *potassio-manganic salt*, $6\text{K}^2\text{O}\cdot\text{Mn}^{\text{O}^2}\cdot 16\text{MoO}^3\cdot 12\text{H}^2\text{O}$ or $\text{Mn}^{\text{O}^2} \left. \begin{matrix} \text{K}^3 \\ \text{H}^6 \end{matrix} \right\} \text{Mo}^{\text{O}^2}\cdot 2\text{H}^2\text{O}$, is prepared, either by boiling manganic hydrate with trimolybdate of potassium, or

better, by passing chlorine through a hot solution of potassic trimolybdate, and gradually adding small quantities of manganous sulphate, as long as the solution is thereby rendered darker in colour. The filtered liquid yields the double salt, after cooling or concentration, in shining orange-coloured rhombohedrons, having the angle of their terminal edges = $107^{\circ} 45'$. It dissolves in 384.3 pts. water at 17° , more easily in boiling water, by which however it is partially decomposed. It gives off 9 at water at 100° , 2 at. more at 160° , acquiring at the same time a darker colour; melts at a higher temperature, and solidifies on cooling into a brownish-red crystalline mass. With nitrate of silver, it forms a precipitate containing molybdic acid, manganic oxide, and silver-oxide, which decomposes during washing. (Struve.)

Molybdates of Silver.—*a.* Neutral argentic molybdate, Ag^2MoO_4 , is obtained by precipitating the neutral potassium-salt with nitrate of silver as a yellowish-white, flocculent precipitate, which darkens on exposure to light, dissolves sparingly in water, easily in dilute nitric acid.—*b.* Trimolybdate of potassium forms with nitrate of silver a yellowish-white flocculent precipitate, of somewhat variable composition, but agreeing best with the formula $2\text{Ag}^+\text{MoO}_4 \cdot 3\text{KMoO}_4$. (Svanberg and Struve.)

Argentous molybdate, $\text{Ag}^+\text{O} \cdot 2\text{MoO}_3 = \text{Ag}^+\text{MoO}_4$, is produced by the action of hydrogen gas at ordinary temperatures on the neutral argentic salt; or better, by passing hydrogen gas through a tube having a narrow aperture, into a saturated solution of the argentic salt in moderately strong aqueous ammonia; the reduction then also takes place at ordinary temperatures, but much more quickly at 90° (at higher temperatures some of the silver may be reduced to the metallic state). By the first method it is obtained as an amorphous mass; by the second, as a black, shining, crystalline powder, consisting of regular octahedrons. It is dissolved by nitric acid, with evolution of nitric oxide, and decomposed by potash (not by dilute ammonia) with separation of black argentous oxide. (Wöhler, Ann. Ch. Pharm. cxiv. 119.)

Molybdates of Sodium.—The neutral or disodic molybdate, $\text{Na}^2\text{MoO}_4 \cdot \text{H}_2\text{O}$ (commonly called the monomolybdate), is obtained by fusing molybdic anhydride with an equivalent quantity of crystallised carbonate of sodium. It is easily soluble in water, and crystallises in small octahedrons, which melt and give off their water at a moderate heat. *Sodio-hydric molybdate*, NaHMoO_4 (or *dimolybdate*, $\text{Na}^+\text{O} \cdot 2\text{MoO}_3 \cdot \text{H}_2\text{O}$), obtained in a similar manner, crystallises in needles, and dissolves sparingly in cold, readily in boiling water. The *disodio-tetrahydric molybdate*, $\text{Na}^2\text{H}^2\text{MoO}_4 \cdot 5\text{H}_2\text{O}$ (or *trimolybdate*, $\text{Na}^+\text{O} \cdot 3\text{MoO}_3 \cdot 7\text{H}_2\text{O}$), is obtained, by adding nitric acid to a solution of molybdic acid in carbonate of sodium, as a bulky white precipitate, more soluble than the corresponding potassium-salt. Nitric acid, added in excess to a solution of molybdate of sodium, throws down nothing but molybdic anhydride. (Svanberg and Struve.)

Trimolybdate of sodium boiled with alumina, chromic oxide, &c., forms double salts analogous to the potassium-salts above described.

Molybdate of Strontium is obtained in well-developed square pyramids by fusing together 1 pt. molybdate of sodium, 2 pts. chloride of strontium and 2 pts. common salt. (Schultze.)

Molybdate of Zinc, Zn^2MoO_4 , is obtained by fusing 2 pts. molybdate of sodium with 3 pts. chloride of zinc and 6 pts. common salt, in white needles, with a tinge of yellow, appearing under the microscope as square prisms, also exhibiting the combination P. ∞ P; fusible without decomposition before the blowpipe. (Schultze.)

MOLYBDENUM, OXYBROMIDES OF. *Molybdous Oxibromide*, $\text{Mo}^2\text{Br}^+\text{O}$, is produced by heating molybdous bromide with dilute solutions of caustic alkalis; when treated with hydrochloric, hydriodic and hydrobromic acid, it yields molybdous chlorobromide, &c. (Blomstrand, see p. 1029.)

Permolybdic Oxibromide, $\text{Mo}^6\text{Br}^+\text{O}_2$, is produced by passing bromine vapour over the heated dioxide, or by fusing molybdic trioxide with boric or phosphoric anhydride, and heating the pulverised mass with bromide of potassium:

When quickly sublimed, it forms indistinct crystalline scales; by slow sublimation, more fully developed crystalline plates. It has a yellowish-red colour and fatty lustre, deliquesces in the air, and forms a colourless solution with water. (Blomstrand.)

MOLYBDENUM, OXYCHLORIDES OF. *Molybdous Oxychloride*,

$\text{Mo}^2\text{Cl}^+\text{O}$, is produced in the same manner as the corresponding oxibromide, and reacts in a similar manner with hydrochloric acid, &c. (Blomstrand, p. 1039.)

Permolybdic Oxychlorides. *a.* $\text{Mo}^6\text{Cl}^+\text{O}_2$ or $\text{MoCl}^+\text{O}_2 \cdot 2\text{MoO}_3$.—Discovered by

Berzelius, first correctly analysed by H. Rose (Pogg. Ann. xl. 399). It is produced in the amorphous state, when any other chlorine-compound of molybdenum is heated in contact with the air, and when the same compounds are exposed to moist air, even at ordinary temperatures (Blomstrand, Jahresb. 1867, p. 193). In the crystalline state it is obtained by the following processes: 1. By passing chlorine over the heated dioxide (Berzelius).—2. By pouring strong sulphuric acid on a mixture of molybdic trioxide and potassic sulphate, evaporating the *excess* of acid in a retort as completely as possible, then adding chloride of sodium, and heating again, whereupon the oxychloride sublimes; but this process does not yield so pure a product as the first (H. Rose).—3. By repeated sublimation of the brown oxychloride (Blomstrand).—4. By subliming a mixture of this brown compound and the amorphous modification of α (Blomstrand). It forms yellowish-white, delicate, crystalline scales (Berzelius); thin, translucent, nearly square plates of pale-reddish colour, or if obtained by the fourth method, thicker crystals of honey-yellow colour and scarcely translucent (Blomstrand). Tastes sharp and astringent, with sweetish after-taste; volatilises, without fusing, at a heat below redness; and is resolved by water into molybdic and hydrochloric acids, both of which remain dissolved; it is soluble also in alcohol.

A hydrate of the preceding compound, $\text{MoCl}^2\text{O}^3 \cdot \text{H}_2\text{O}$, which may also be regarded as a *hydrochlorate of molybdic trioxide*, $\text{MoO}^3 \cdot 2\text{HCl}$, is obtained by passing hydrochloric acid gas over the trioxide heated to 150° — 200° , as a white crystalline, very volatile substance, which is resolved by heat into hydrochloric acid and trioxide of molybdenum, but may be volatilised without decomposition in hydrochloric acid gas. It dissolves easily in water, but the solution when evaporated leaves nothing but molybdic trioxide (Debray, Ann. Ch. Pharm. xviii. 250). The permolybdic sulphate, nitrate, &c., described at p. 1037, are perhaps analogous in constitution to the compound just mentioned, but they have not been analysed.

β . $\text{Mo}^2\text{Cl}^4\text{O}$ or $2\text{MoCl}^2 \cdot \text{MoO}^3$?. This is a green, easily fusible oxychloride, obtained by passing chlorine over an intimate mixture of molybdic oxide and charcoal (or even imperfectly reduced molybdenum still containing oxygen) heated by a common spirit-lamp. The bulky amorphous oxychloride which first forms is to be removed, and the sublimate which forms when the vapour has acquired a permanent blood-red colour is to be collected. It is indistinctly crystallised in dark green tufts; if formed at a somewhat stronger heat, in light green metallic-shining scales. It melts and volatilises below 100° , forming a dark red-brown vapour, and is decomposed by water, yielding hydrochloric acid and blue oxide of molybdenum. Hence, and from the results of analysis, Blomstrand regards it as $\text{Mo}^2\text{Cl}^2\text{O}^3$ or $2(\text{MoCl}^2 \cdot 2\text{MoCl}^2) + \text{MoO}^3 \cdot 2\text{MoO}^3$, but observes that the analytical numbers do not differ much from those required by the simpler formula above given.

γ . $\text{Mo}^2\text{Cl}^2\text{O}^3 = (\text{MoCl}^2 \cdot \text{MoCl}^2) \cdot (\text{MoO}^3 \cdot \text{MoO}^3)$. This is a brown, easily fusible substance, produced by the action of chlorine on a mixture of charcoal and sesquioxide of molybdenum (formed from the trioxide by the prolonged action of hydrogen at a red-heat, or by the reducing action of zinc in the wet way). The latter part of the product is collected apart and purified by fractional sublimation in an atmosphere of hydrogen. When very slowly sublimed, it forms large brown or black-brown crystals. (Blomstrand.)

δ . $\text{Mo}^2\text{Cl}^2\text{O}^3 = \text{MoCl}^2 \cdot \text{MoO}^3$. Produced, though only occasionally and in small quantity, by the action of chlorine at a moderate heat on a mixture of molybdic oxide and charcoal, accompanying the green oxychloride β , which is formed towards the latter part of the process. It may be freed from the latter, and from any other compounds that may be present, by its inferior volatility. It forms well-defined prismatic crystals of a dark violet colour by reflected, ruby-red by transmitted light; it volatilises with difficulty, but without previous fusion. Water first dissolves it with slight rise of temperature, and then throws down a white precipitate, soluble in a larger quantity of water.

MOLYBDENUM, PHOSPHIDE OF. Mo^2P^2 .—A mixture of 1 pt. yellow trioxide of molybdenum containing phosphoric acid, and 2 pt. fused phosphoric acid containing lime, is exposed for an hour in a charcoal crucible to the heat of a very strong coke fire, whereby a gray blistered mass is formed, consisting of small metallic-shining crystals of phosphide of molybdenum, mixed with calcic phosphate, and having its cavities lined with the same crystals.

Phosphide of molybdenum forms a powder of specific gravity 6.167. The crystals conduct electricity. It is very difficult to fuse; oxidises gradually in the air without burning, but with incandescence on melting *nitre*. By hot *nitric acid* it is converted into phosphoric and molybdic acids, and dissolved. When gently heated in *chlorine gas*, it is converted, without visible combustion, into chloride of molybdenum and

chloride of phosphorus. In contact with zinc it eliminates hydrogen from *hydrochloric acid*, and on addition of a *copper-salt*, reduces copper on its surface. (Wöhler and Rautenberg, Ann. Ch. Pharm. cix. 374.)

MOLYBDENUM, SULPHIDES OF. Molybdenum unites with sulphur in three proportions, forming the compounds MoS_2 , MoS_3 , and MoS_4 . The last two are sulphur-acids. Our knowledge of these sulphides and their salts is almost wholly due to the researches of Berzelius.

Disulphide or Molybdic Sulphide. MoS_2 .—This compound occurs native as *Molybdenite* (*Molybdänglanz*, *Wasserblei*), generally in crystallo-laminar masses, more rarely in tabular crystals, $\infty \text{P} \cdot \text{oP}$, belonging to the hexagonal system, cleavable parallel to oP . Hardness = 1 to 1.5; easily impressed by the nail. Specific gravity = 4.44 to 4.8. The mineral has a strong metallic lustre and pure lead-grey colour; streak similar, but slightly inclined to green; it forms a grey trace on paper, and a greenish trace on porcelain. It is opaque, sectile, and almost malleable; laminæ highly flexible and elastic.

Molybdenite is of frequent occurrence in primitive rocks, being sometimes found in metalliferous veins, especially of magnetic iron ore and tin ores. It is found in Cornwall, at Caldbeck Fell in Cumberland, in Saxony, Bohemia, Sweden, Norway, and Greenland, and at numerous localities in the United States. It occurs nearly pure, but according to Svanberg and Struve, generally contains a small quantity of phosphoric acid (or phosphorus), a fact which must be borne in mind when the mineral is used for the preparation of molybdate of ammonium.

Disulphide of molybdenum is produced artificially by heating either of the higher sulphides, also by igniting the trioxide with sulphur. The artificial sulphide is a black shining powder.

The disulphide heated in closed vessels, sustains a high temperature without fusing or undergoing any change, and according to H. Rose, is not decomposed by ignition in dry hydrogen gas. When heated in the air, it is converted into molybdic anhydride, with evolution of sulphurous anhydride. Before the blowpipe on charcoal it gives off sulphurous anhydride, covering the charcoal with a yellowish-white incrustation; but it burns with great difficulty, and the combustion is but imperfect. On platinum wire it colours the outer blowpipe flame green. It colours a bead of borax, mixed with nitre, dark brown in the inner flame, and light brown in the outer.

It decomposes vapour of water at a red heat slightly, but at a higher temperature with greater facility. It detonates with nitre, forming a molybdate of potassium; dissolves readily in warm *nitromuriatic acid*, producing molybdic and sulphuric acids, is easily oxidised by *nitric acid*; dissolves in boiling oil of vitriol with evolution of anhydride, and forms a blue solution.

Trisulphide. *Sulphomolybdic acid.* MoS_3 .—This compound, the analogue of the trioxide, is formed by decomposing that compound with sulphydric acid, viz. (1) by passing the gas into a concentrated solution of an alkaline molybdate and precipitating with an acid; or (2) by adding sulphide of ammonium to the solution and then hydrochloric acid, both in excess. The whole of the molybdenum is then precipitated as trisulphide, which settles down quickly, and must be rapidly washed on a filter with water containing sulphydric and hydrochloric acids, to prevent oxidation. As thus obtained it is a black-brown powder which makes a dark brown streak on porcelain. When heated it gives off sulphur, and is converted into the disulphide. It dissolves, but not readily, in caustic alkalis, more easily at the boiling heat, undergoing partial decomposition at the same time. It is most easily dissolved by *alkaline monosulphides* and *sulphhydrates*, forming sulphur-salts called *sulphomolybdates*; the alkaline disulphides do not dissolve it.

The *sulphomolybdates* are the analogues of the molybdates, most of them being constituted according to the formula $\text{R}^2\text{S.MoS}_3$ or R^2MoS_4 . There are also a few containing 2 or 3 at. of the sulphur-acid. The *sulphomolybdates* of the alkali-metals, alkaline earth-metals, and magnesium, are soluble in water; the rest are insoluble. The alkali-metal salts are obtained by passing sulphydric acid gas into concentrated solutions of the corresponding molybdates; the insoluble salts by precipitating a neutral oxygen-salt of the metal with a soluble *sulphomolybdate*.

The aqueous solutions of neutral *sulphomolybdates* have a fine red colour when pure, changing to brown, however, if they contain a small quantity of iron or an excess of the sulphur acid. During evaporation, they emit a constant odour of sulphydric acid. When exposed to the air, they remain unaltered, if they contain an excess of the sulphur-acid; in the contrary case, the solutions—and likewise the dry salts—are rapidly oxidised, the sulphide of the alkali-metal being converted into hypsulphite, while the trisulphide of molybdenum is partly precipitated as such, partly converted into trioxide and blue oxide of molybdenum. The *sulphomolybdates* are decomposed by acids.

with evolution of sulphydric acid and precipitation of molybdic trisulphide. When heated to redness, they yield molybdous sulphide and a disulphide of the base, or give off 1 at. sulphur.

Sulphomolybdate of Ammonium, $(\text{NH})^2\text{MoS}^4$, separates from a concentrated aqueous solution mixed with alcohol in cinnabar-coloured scales, becoming dark brown on exposure to the air. The aqueous solution, if left to evaporate, yields at the edges a number of crystals which are green by reflected light, while in the middle it dries up to a black amorphous mass. The salt is sparingly soluble in alcohol.

Bodenstätt (J. pr. Chem. lxxviii. 186; Jahresb. 1859, p. 163), by passing sulphydric acid gas to supersaturation into a solution of impure molybdic acid in hydrochloric acid, mixed with a large quantity of sal-ammoniac and previously supersaturated with ammonia, obtained deep red crystals of a *sulphoxymolybdate*, $(\text{NH})^2\text{MoO}^2\text{S}^2$.

Sulphomolybdates of Barium.—The neutral salt, Ba^2MoS^4 , is obtained, as a dark red amorphous mass, from the mother-liquor of the following salt. The *trisulphomolybdate*, $\text{Ba}^2\text{S}_3\text{MoS}^3$ or $\text{Ba}^2\text{MoS}^4\cdot 2\text{MoS}^3$, is obtained by boiling sulphide of barium with an excess of molybdic trisulphide, and separates from the hot filtrate on cooling, in small yellow shining crystals, which, when laid on paper, crumble to a shining powder of the same colour. They give off water, and turn red when heated, and are decomposed by dilute, but not by concentrated hydrochloric acid.

The *cadmium-salt* is a dark brown precipitate insoluble in water.

An acid *calcium-salt*, probably $\text{Ca}^2\text{MoS}^4\cdot 2\text{MoS}^3$, is obtained like the corresponding barium-salt, and crystallises in short, shining, vermilion-coloured, needle-shaped crystals, permanent in air even at 100° ; hydrochloric acid blackens them by separating the sulphide of molybdenum. The mother-liquor of this salt, when evaporated, leaves the neutral calcium-salt in the form of a dark red varnish.

Cerous sulphamolybdate is a dark grey precipitate. On adding an alkaline sulphomolybdate to the solution of a ceric salt, only a slight precipitate is formed, but ammonia throws down from the resulting yellow solution a basic salt in the form of a brown gummy mass.

The *chromic salt* is a dark brown precipitate, which turns green in drying. The *cobalt- and copper-salts*, are dark brown precipitates, the former soluble in sulphide of potassium.

The *gold-salt (auric)* is soluble in water, whence it separates after some time as a dark brown powder, becoming black when dry.

Iron-salts.—The *ferrous salt* is soluble in water, forming a wine-red solution, which becomes darker and nearly black on exposure to the air; when evaporated in a shallow vessel, together with sulphomolybdate of potassium, it ultimately separates from the latter as a black jelly, which, as well as the dilute solution, deposits a pale red-yellow powder by spontaneous evaporation. The *ferric salt* is a dark red precipitate which dissolves, with black colour, in excess of sulphide of potassium, but generally separates again after 24 hours. When dry it is black and yields a brown powder.

The *lead-salt* is a black precipitate, which when dry, forms a lead-grey, metallic-shining streak on paper.

Magnesium-salts.—By boiling molybdic trisulphide with sulphhydrate of magnesium, and cooling, a dark brown powder is obtained, consisting of an *acid sulphomolybdate of magnesium*. The supernatant liquid contains the neutral-salt and dries up to a dark red varnish.

Manganese-salts.—By digesting sulphide of manganese in excess with molybdic trisulphide, a brownish-yellow liquid is obtained, which dries up to a transparent varnish. Ammonia throws down from the solution a red basic salt, which is decomposed by a larger quantity of ammonia. Sulphide of manganese digested with excess of molybdic trisulphide forms an insoluble compound.

Mercury-salts.—*Mercurous sulphomolybdate* is a nearly black, the *mercuric salt* a light brown precipitate. The *nickel-salt* resembles the cobalt-salt. The *platinum-salt* is a dark brown precipitate, black after drying.

Potassium-salts.—a. The *neutral salt*, K^2MoS^4 , is produced by heating a mixture of potassic carbonate, sulphur, charcoal powder and excess of molybdic trisulphide in a crucible, gently at first, afterwards very strongly. The black unfused mass yields with water, after cooling, a dark red opaque solution. A similar solution is obtained by saturating a solution of potassic molybdate with sulphydric acid. When evaporated in a cylindrical vessel at 40° , it yields four and six-sided prisms, with dihedral angles, which are dark red by transmitted, but of a fine dark green colour by reflected light, and yield a dark red powder, becoming green and shining by pressure. Alcohol added to the red aqueous solution, throws down a cinnabar-coloured powder, and the mixed liquid deposits scales of the same colour which acquire a green metallic lustre by

drying. The salt heated in an atmosphere of hydrogen is only partially decomposed into disulphide of potassium and molybdous sulphide.—*β*. Another salt containing a larger proportion of molybdic trisulphide, is precipitated as a brown-yellow powder, when the solution of the neutral salt is mixed with a quantity of acetic acid sufficient to give it an acid reaction. It is black after drying, and dissolves easily in boiling, slowly in cold water, forming a yellow solution. A solution of the neutral salt, mixed with a small quantity of any other acid, becomes darker, in consequence of the formation of this compound, but does not yield a precipitate.

A compound of *sulphomolybdate* and *nitrate of potassium* is obtained when a solution of equal parts of the two salts is left to evaporate. It then separates in green metallic-shining scales, very much like *sulphomolybdate of potassium*, which burn away like gunpowder when heated.

The *silver-salt* resembles the lead-salt in colour and streak.

Sodium-salts.—The *neutral salt* forms small dark red granular crystals, much more soluble in alcohol than the potassium-salt. It is almost completely reduced by ignition in hydrogen gas. There is also an *acid sulphomolybdate of sodium*, much less soluble than the neutral salt, and resembling the corresponding potassium-salt in all its properties.

The *strontium-salts* resemble the barium-salts.

The *uranium-* and *zinc-salts* are dark brown precipitates; the *stannous* salt is a black precipitate; the *stannic* salt, a translucent brown precipitate becoming grey-brown when dry.

Tetrasulphide of Molybdenum. *Persulphomolybdic acid*, MoS_4 .—This sulphide is thrown down by hydrochloric acid from the solutions of alkaline persulphomolybdates, as a flocculent translucent precipitate of a fine dark red colour, shrinking together when dry, into a coarse-grained mass, possessing a dark green metallic lustre, and yielding a dark red powder when triturated with water. It is insoluble in water and in acids. When heated in a retort, it gives off water and a small quantity of sulphurous anhydride, then a large quantity of sulphur, and leaves disulphide of molybdenum.

Persulphomolybdates. Tetrasulphide of molybdenum unites with basic metallic sulphides, forming salts represented by the formula $\text{R}^{\text{b}}\text{S}.\text{MoS}_4 = \text{R}^{\text{b}}\text{MoS}_4$. Most of them are dark red and retain their colour unaltered when dry. The *persulphomolybdates of the alkali-metals* are soluble in water, and their solutions yield with acids a precipitate of molybdic tetrasulphide.

The *ammonium-salt* is obtained by drenching moist molybdic tetrasulphide with sulphhydrate of ammonium, to which a little caustic ammonia may be advantageously added. A yellow powder is then formed, which becomes dark red when dry, is insoluble in alkaline liquids, sparingly soluble in cold, easily in hot water.

Barium-salt.—Yellow or red precipitate, insoluble in water, and not decomposed by dilute hydrochloric acid. The *calcium-salt* is precipitated after some time by alcohol from a mixture of the potassium-salt with chloride of calcium, as a cinnabar-coloured powder slightly soluble in water.

The *copper-salt* is a precipitate dark coloured at first, but becoming red inclining to brown after it is collected. The *gold-salt* (auric) is a brown precipitate which turns yellow and decomposes in drying, and when heated in contact with the air, burns, gives off sulphurous anhydride, assumes a golden-yellow colour, and when very strongly heated, yields a sublimate of molybdic trioxide.

Iron-salt.—Red precipitate formed on adding the potassium-salt to an excess of a ferrous salt.

The *lithium-salt* resembles the potassium-salt. The *magnesium-salt* is an insoluble red precipitate.—The *mercurous salt* is a dark almost brown precipitate.

Potassium-salts.—When *sulphomolybdate of potassium* is boiled with molybdic trisulphide (such a mixture is obtained by decomposing an acid molybdate of potassium with sulphydric acid), the boiling being continued for several hours in a retort, a large quantity of sulphydric acid is given off with the watery vapours, and a copious precipitate is formed. On collecting the precipitate after cooling on a filter and washing till the wash-water gives a dark red flocculent precipitate with hydrochloric acid, a residue is obtained from which water extracts *persulphomolybdate of potassium*, leaving disulphide of molybdenum behind. The resulting solution is red, and generally yields the salt on evaporation in the form of a red mass, having the consistence of an extract. On one occasion, however, Berzelius observed the salt to separate from the boiled mixture on cooling, in small ruby-coloured crystalline granules which could be separated from the rest of the precipitate by levigation. They appeared under the microscope as transversely striated rectangular scales; were

insoluble in cold water, hydrochloric acid, and potash, but soluble in hot water. At a low red heat, they decrepitated, gave off water, a small quantity of sulphur, and sulphydric acid, after which water extracted sulphide of potassium from them, leaving disulphide of molybdenum.

When a dilute solution of sulphomolybdate of potassium containing an excess of molydic trisulphide is exposed to a heat of 60° — 80° , it becomes turbid and gradually yields a lighter coloured deposit of persulphomolybdate of potassium, which, after drying, forms a yellow coherent mass consisting of small crystalline particles having a silky lustre. The same mass is obtained by drenching molybdic tetrasulphide with sulphhydrate of potassium. It is insoluble in cold, but soluble in hot water.

Persulphomolybdate of silver is a dark brown precipitate, black when collected.

The *sodium-* and *strontium-salts* resemble the potassium- and barium-salts respectively.

Tin-salts.—The *stannous salt* is obtained from stannous chloride by double decomposition, as a dark brown precipitate. If the mixture be left for several days in an open vessel, the stannic salt is formed and the supernatant liquid becomes red.—The *stannic salt* is only partially precipitated, the rest remaining dissolved with the same colour.

MOLYBDIN. Syn. with molybdic ochre, or native trioxide of molybdenum.

MOMORDICA. According to Lepine (J. Pharm. [3] xl. 16), *Momordica charantia* yields a solid fat melting at 65° .—On the amount of elaterin contained in the fruit of *Momordica Elaterium* at different seasons, see Walz (N. Jahrb. Pharm. xi. 21).

MOMORDICIN. Syn. with ELATERIN (ii. 373).

MONARDA, OIL OF. The essential oil of an American Labiate plant, the *Monarda punctata*. It easily separates into a liquid oil and a camphor. The oil or essence is a yellowish-red liquid, having an odour of thyme, becoming light yellow after rectification with water, boiling at 224° , and easily resinising by oxidation. The camphor or stearoptene, when purified by pressure and distillation, forms shining crystals, melting at 48° and solidifying again at 38° . Its composition, according to Arppe's analysis, is $C^{10}H^{14}O$; that of the oil separated from the stearoptene appears to be $(C^{10}H^{11})^2O$. The crystals absorb 2 or 3 per cent. hydrochloric acid gas. (Arppe, Ann. Ch. Pharm. lvi. 41; Handw. d. Chem. v. 377.)

MONAZITE. *Edwardsite, Mengite, Eremite*.—A phosphate of cerium and lanthanum, also containing thorium according to some authorities, occurring in monoclinic prisms, usually small and flattened. Ratio of axes, $a : b : c = 1.0265 : 1 : 0.94715$. Angle of b and $c = 76^{\circ} 14'$. Observed planes, $\infty P\infty$, $[\infty P\infty]$, $+P\infty$, $-P\infty$, $+P$, $-P$, ∞P , $[\infty P2]$, and others. Cleavage basal, very distinct and brilliant. Hardness = 5 to 5.5. Specific gravity = 4.9 to 5.25. The crystals have a brownish-red, hyacinth-red, or yellowish-brown colour, and resinous lustre; they are subtransparent to subtranslucent and rather brittle. The mineral is infusible before the blowpipe; dissolves slowly in borax, forming a bead which is yellowish-green or yellowish-red while hot, colourless when cold.

Analysis.—a. From Slatoust in the Ural; Brooke's *Mengite* (Kersten, Pogg. Ann. xlvii. 385).—b. The same (Hermann, J. pr. Chem. xxxiii. 90).—c. Rio Chico, Antioquia, in New Granada:

P ² O ⁵ .	ThO.	CeO.	LaO.	CaO.	MgO.	MnO.	SnO ² .	
28.50	17.95	24.78	23.40	1.68		1.86	2.10	= 100.27*
28.05		37.36	27.41	1.46	0.80		1.75	= 96.83
29.1		46.4	24.5					= 100.00

The presence of thorium in monazite has been confirmed by Berzelius and Wöhler. Hermann, on the contrary, denies it, and is of opinion that a basic sulphate of cerium formed in the analysis has been mistaken for sulphate of thorium. The analytical results may be represented by the formula $(Ce; La)P^{2}O_6$ or $(Ce; La; Th)P^{2}O_6$; but new analyses are required to fix the formula with certainty.

Monazite was first obtained from Slatoust. It occurs also at Norwich and Water-town in Connecticut; at Yorktown, Chester County, New York; and near Crowder's Mountain, North Carolina.

MONAZITOID. The name given by Hermann (J. pr. Chem. xl. 20) to a variety of monazite from the Ural, distinguished by its brown colour, higher specific

* With traces of uranic acid and potash.

gravity (= 5.281), and by the presence of tantalum. Hermann found in it 17.94 per cent. P_2O_5 , 49.35 CaO, 21.30 LaO, 1.60 CaO, 1.36 H_2O , and 6.27 TaO $_3$. It gives off a small quantity of chlorine when treated with hydrochloric acid, and dissolves, leaving a considerable yellow residue.

MONESIN. A compound resembling saponin, contained in an extractive substance called *Monesia*, which appears to be obtained from the bark of *Chrysophyllum glycyphaeum*, a Brazilian plant of the sapotaceous order. (Desrone, Henry and Payen, Ann. Ch. Pharm. xxxvii. 352.)

MONHEIMITE. Syn. with KAPNITE (p. 445).

MONO-COMPOUNDS. This term is applied to compounds containing 1 at. of the element specified, e.g., $C^2H^3ClO^2$, *monochloracetic acid*, $C^6H^3.H^2.N$, *monophenylamine*, &c.

MONOPHANE. Syn. with EPISTILBITE (ii. 491).

MONOTROPA. According to F. L. Winckler (N. Jahrb. Pharm. viii. 322), the herb of *Monotropa hypopitys*, gathered when the flowers are almost fully expanded, yields by distillation with water, a volatile oil identical with that of *Gaultheria procumbens* (ii. 825). The residue of the distillation contained an acid.

MONRADITE. A magnesio-ferrous silicate from Bergen in Norway, where it occurs massive granular; also foliated, with one distinct and another imperfect cleavage inclined at 130° . Hardness = 6 nearly. Specific gravity = 3.2673. It has a pale yellow colour inclining to red, and a strong vitreous lustre. Contains 56.17 per cent. silica, 31.63 magnesia, 8.56 ferrous oxide, and 4.04 water (= 100.40, agreeing nearly with the formula $4(\frac{1}{2}Mg.\frac{1}{2}Fe)SiO_3.H_2O$. (Erdmann, K. Vet. Acad. Handl. 1842; Dana, ii. 280.)

MONROLITE. Syn. with KYANITE (p. 449).

MONTANINE. An alkaloid said by Van Mons to exist in *China montana*, the bark of *Exostemma floribundum*. Winckler was not able to find it.

MONTICELLITE. A variety of chrysolite (i. 958).

MONTMORILLONITE. A rose-red, fragile, argillaceous substance found at Montmorillon near Confolens in Charente, and near St. Jean de Colle in Dordogne. Contains 50.04 per cent. silica, 20.16 alumina, 0.68 ferric oxide, 1.46 lime, 0.23 magnesia, 1.27 potash, and 26.0 water. (Damour, Bull. Soc. geol. de France [2] iv. 404.)

MOONSTONE. A variety of translucent felspar from Ceylon. (See FELSAPAR, ii. 620.)

MORDANTS. See DYING (ii. 352).

MORDENITE. A fibrous zeolite from the trap of the Bay of Fundy, Nova Scotia, the name being derived from *Morden*, a village near which it is found. It occurs in small concretions or geodes of white, yellowish or pinkish colour, and strong silky lustre, weathering dull; cleaves readily in directions parallel to the fibres; is translucent on the edges. Hardness a little above 5. Specific gravity = 2.08. Rather brittle. Before the blowpipe it fuses at a strong heat to a glassy bead, without intumescence; with hydrochloric acid it does not gelatinise but yields slimy silica. Contains (mean of analyses) 68.40 per cent. silica, 12.77 alumina, 3.46 lime, 2.35 soda, and 13.02 water (= 100), agreeing very nearly with the formula, $(\frac{1}{2}Na.\frac{1}{2}Ca)O.Al_2O_3.98SiO_2.6H_2O$, which is reducible to that of a metasilicate, $M^2(R^2)^2H^2Si_2O_7.H_2O$. (How, Chem. Soc. J. xvii. 104.)

MORIC ACID. *Morin*. (R. Wagner, J. pr. Chem. li. 82; Hlasiwetz and Pfaundler, *ibid.* xc. 445.)—An acid existing in old fustic (*Morus tinctoria*), and deposited as a calcium-salt, together with morintannic acid, from an infusion of the wood on cooling. To extract it, the deposit (sometimes called *morin*) is treated several times with boiling alcohol; the alcoholic liquor is diluted with six times its bulk of water, which precipitates the morate of calcium in the form of a yellow crystalline powder, while the whole of the morintannic acid remains dissolved. The calcium-salt is then dissolved in boiling alcohol, the calcium precipitated by oxalic acid, and the moric acid is separated from the hot filtrate by water, purified by re-solution in alcohol and re-precipitation by water, and finally dried over the water-bath out of contact with air (Wagner). Hlasiwetz and Pfaundler treat the deposit above mentioned twice with boiling water, after pressing it, and thereby obtain a solution of morintannic acid (p. 1045), and a residue consisting of crude moric acid and nitrate of calcium. This residue is heated with water and a little hydrochloric acid (to decompose the calcium-salt), then washed with water and dissolved in hot alcohol. The filtrate mixed with two-thirds of its volume of hot water, deposits the greater part of the moric acid in yellow crystals, which may be purified by solution in weak alcohol (using filters

free from lime and iron), and formation of a small quantity of lead-sulphide in the solution, to carry down resinous matters.

Moric acid is a white crystalline powder, which gradually turns yellow in contact with the air. According to Hlasiwetz and Pfandler, it crystallises in needles several lines long, mostly grouped in tufts. It is very sparingly soluble in water, requiring 4000 pts. at 20° and 1060 pts. at 100° to dissolve it; very soluble in alcohol and in ether (Wagner), sparingly soluble in ether, insoluble in sulphide of carbon (Hlasiwetz and Pfandler). The solutions have a deep yellow colour, and slight acid reaction. Dried at 120°, it contains, according to Wagner, 55.2 per cent. carbon, and 3.2 hydrogen, numbers which may be represented by the formula $C^{12}H^{14}O^2.H^2O$. This composition differs but little from that of morintannic acid; indeed Delffs (Zeitschr. Chem. Pharm. 1862, p. 143) concludes, from his own experiments, that Wagner's moric acid is nothing but morintannic acid contaminated with colouring matter. On the other hand, Wagner (Chem. Centr. 1862, p. 399) still maintains the distinctness of moric from morintannic acid, inasmuch as the former is colourless, much less soluble in water than the latter, and reacts differently with alkalis. The difference between the two acids is further established by the experiments of Hlasiwetz and Pfandler.

Moric acid bears a rather high temperature without decomposing. At 300° it blackens and gives off a considerable quantity of carbonic anhydride, together with a yellow oil which partly concretes on cooling, and consists of a mixture of phenol and oxyphenic acid (pyrocatechin). It dissolves in weak acids without coloration; in strong sulphuric acid with brown-yellow colour, and is precipitated by water in its original state. The sulphuric acid solution decomposes when heated, giving off sulphurous anhydride and phenol. Strong nitric acid converts moric acid into oxypticric acid. With caustic alkalis and their carbonates, moric acid forms solutions of a fine yellow colour: paper impregnated with it affords a delicate test for free alkalis. The solution does not precipitate gelatin, but it stains animal skin yellow. Ferric chloride colours the solution garnet-red (Wagner), deep olive-green (Hlasiwetz and Pfandler). A solution of moric acid boiled with cupric sulphate or acetate, after addition of potash, yields a precipitate of cuprous oxide. From an ammoniacal solution of silver-nitrate, it immediately reduces metallic silver.

Morate of Barium is produced by boiling the acid with recently precipitated carbonate of barium: the resulting solution when evaporated yields the salt in the form of a red-brown powder, apparently containing $3C^{12}H^{14}BaO^2.C^{12}H^{14}O^2.H^2O$. The calcium-salt exists ready formed in fustic, and is deposited from its alcoholic solution in sulphur-yellow crystals which apparently contain $C^{12}H^{14}CaO^2.H^2O$, and give off their water at 100°. (Wagner.)

MORINDIN. A substance obtained by Anderson (Ed. Phil. Trans. xvi. [6] 436; Ann. Ch. Pharm. lxxi. 216) from the root of *Morinda citrifolia*, the "Al" root of the Hindoos, frequently used as a dye-stuff in the Madras Presidency. When this root is exhausted with boiling alcohol, the first decoctions deposit brown flocks of morindin contaminated with a red colouring matter, but the last portions yield it in small radiated yellow crystals. The whole is purified by repeated crystallisation from dilute alcohol slightly acidulated with hydrochloric acid.

Morindin forms crystals having a fine yellow colour and satin lustre. It is sparingly soluble in cold, more soluble in boiling alcohol, especially when dilute; in absolute alcohol it is less soluble, and quite insoluble in ether. Cold water dissolves it but sparingly, sufficiently however to acquire a yellow colour; boiling water dissolves it easily, and deposits it on cooling as a gelatinous mass, destitute of crystalline structure.

Morindin dried at 100° gives by analysis 55.4 per cent. carbon and 5.1 hydrogen, whence Anderson deduces the formula $C^{55.4}H^{5.1}O^{13}$ or $C^{12}H^{12}O^{13}$ (requiring 55.4 per cent. C, 4.9 H, and 39.6 O). Rochleder regards it as identical with the ruberythric acid (54.5 C, 5.2 H, 40.3 O), which he obtained from madder.

Morindin dissolves in alkalis, forming orange-red solutions. Strong sulphuric acid colours it deep purple, or violet in thin layers; the solution, if diluted with water after 24 hours, deposits yellow flocks of unaltered substance, quite insoluble in cold water, and forming with ammonia, not an orange-red, but a violet solution.

Nitric acid of specific gravity 1.38 dissolves morindin slowly in the cold, acquiring a deep red colour; on heating the liquid, a brisk reaction takes place; the solution boiled with nitric acid and neutralised with ammonia does not precipitate calcium-salts.

Basic acetate of lead precipitates morindin in crimson flocks, which are not very stable and cannot be washed without loss of colouring matter. Solutions of baryta, strontia and lime form bulky precipitates sparingly soluble in water.

Ferric chloride produces a brown coloration, but no precipitate. An ammoniacal solution of morindin forms with alum a reddish liquid, and with ferric chloride a precipitate having the colour of ferric oxide.

Morindin heated in a close vessel melts and boils, giving off orange-coloured vapours,

which condense in long slender yellowish-red needles of alizarin (Anderson's *morindone*).

When powdered morinda-root is boiled with moderately dilute *sulphuric acid*, as in the ordinary garancin process, its morindin is converted into alizarin; but the large quantity of brown matter produced at the same time, greatly diminishes the value of the dye-stuff obtained, as it renders the colours dull and the whites difficult to clear. The "Al" root is therefore never likely to compete successfully with madder, at least in Europe; nevertheless it affords the best known source of pure alizarin, this substance, when prepared from it, being quite free from purpurin, which, as is well known, is very difficult to separate completely from the alizarin prepared from ordinary madder. (Stenhouse, *Chem. Soc. J.* xvii. 334.)

MORINDONE. See the last article.

MORINGIC ACID. $C^{15}H^{20}O^2$.—An oily acid, homologous with oleic acid, obtained, together with stearic, palmitic and benic acids, by the saponification of oil of ben (*Moringa aptera*). It is colourless or faintly yellow, has a density of 0.908, a mawkish taste, which irritates the throat, and a faint odour. It reddens litmus paper; is very soluble in common alcohol, even in the cold; solidifies at the freezing point of water; is decomposed by heating with sulphuric acid. Walter found in it 75.0 per cent. carbon, and 11.7 hydrogen, the above formula requiring 74.9 C, 11.8 H, and 13.3 O. (*Gerhardt's Traité de Chim. org.* ii. 882.)

MORINTANNIC ACID. *Machurin*. $C^{13}H^{10}O^6$. (R. Wagner, *J. pr. Chem.* li. 82. Hlasiwetz and Pfaunder, *ibid.* xc. 445; *Jahresb.* 1863, p. 594.)—A variety of tannic acid which constitutes the chief colouring matter of old fustic (*Morus tinctoria*, or according to Hlasiwetz and Pfaunder, *Machara tinctoria*). It forms a large portion of the deposits found in the interior of faggots of that wood, and may be obtained by treating these deposits with boiling water and leaving the extract to cool. The acid is then deposited in the form of powder and may be purified by crystallising it several times from pure water, and dissolving the crystalline deposit in water slightly acidulated with hydrochloric acid, to separate a resinous substance, and filtering the solution when it is no longer turbid. (Wagner.)

A strongly concentrated aqueous decoction of fustic left to itself for some days yields an abundant crystalline deposit, which when pressed and twice boiled with water yields a residue consisting of crude moric acid and morate of calcium, and a solution of morintannic acid, which deposits a portion of the acid on evaporation, the rest on addition of hydrochloric acid. It may be freed from resinous impurities, first by crystallisation from water acidulated with hydrochloric acid, and finally by adding to the solution a small quantity of acetate of lead, and precipitating with sulphydric acid in presence of free acetic acid. (Hlasiwetz and Pfaunder.)

Morintannic acid is deposited from its solution as a light yellow crystalline powder, composed of microscopic prisms. It dissolves in 64 pts. of cold, and 2.14 pts. of boiling water, the solution having a slight acid reaction, and sweetish astringent taste; easily also in alcohol, wood-spirit, and ether; but is insoluble in oil of turpentine and in fixed oils. The ethereal solution is greenish by reflected and brown by transmitted light. (Wagner.)

The composition of morintannic acid is shown by the following analyses and calculations:

At 130°—140°.				At 166°.			
Calculation.	Hlasiwetz and Pfaunder.			Calculation.	Wagner, mean.	Delifs.	
C ¹³	59.64	59.36	59.25	C ¹³	55.71	55.17	54.1
H ¹⁰	3.81	4.13	4.18	H ¹²	4.29	4.41	4.4
O ⁶	36.65	36.61	36.67	O ⁷	40.00	40.42	41.5
C ¹³ H ¹⁰ O ⁶	100.00	100.00	100.00	C ¹³ H ¹⁰ O ⁶ .H ² O	100.00	100.00	100.0

Delifs regards the compound dried at 100° as identical with moric acid; but as already observed (p. 1047), the difference between the two acids may be considered as completely established by the recent researches of Hlasiwetz and Pfaunder.

Morintannic acid melts at 200°, blackens and gives off water and acid vapours at 250°, and undergoes complete decomposition at 270°, yielding a large quantity of carbonic anhydride, and an oily distillate which partly solidifies on cooling, and leaving a bulky cinder. The distilled oil is a mixture of phenol and pyrocatechin. (Wagner.)

The aqueous solution of morintannic acid is not precipitated by hydrochloric, sulphuric, phosphoric or arsenic acid, but completely by gelatin and softened animal bladder.

Morintannic acid dissolves in cold strong sulphuric acid, forming a yellow solution from which it is precipitated by water; on heating the solution, it blackens and gives sulphurous anhydride and phenol. The solution in cold sulphuric acid, if left to itself for

some days, yields a brick-red deposit of *rufimoric acid*. This acid is also deposited after a while from the solution of morintannic acid in boiling dilute *hydrochloric acid*. By boiling concentrated *hydrochloric acid*, and by oxidising agents, morintannic acid is decomposed, giving off the odour of phenol. With *peroxide of manganese* and *sulphuric acid*, it gives off a large quantity of carbonic anhydride, together with formic acid. Strong *nitric acid* converts it into styphnic (oxypicric) acid. *Chromic acid* decomposes it easily and completely. *Chlorine* passed into its aqueous solution throws down yellow resinous flocks. (Wagner.)

The acid mixed with a solution of 3 pts. *hydrate of potassium* and evaporated in a silver dish till it has become pasty is resolved into *phloroglucin* and *protocatechuic acid*. (Hlasiwetz and Pfaundler):

Morintannates. Morintannic acid unites directly with caustic alkalis and decomposes the alkaline and earthy carbonates when boiled with them; the solutions of the alkaline morintannates are yellow, but quickly turn brown or black in contact with the air, so that these salts cannot be obtained pure in the solid state. A solution of the acid forms a greenish precipitate with *ferroso-ferrie sulphate*, yellow with *acetate of lead*, brown with *potassio-antimonie tartrate*, yellowish-brown with *cupric sulphate*, yellowish-red with *stannous chloride*, yellow and flocculent with *platinic chloride*. It does not immediately precipitate a solution of *alum*, but on adding carbonate of potassium, a yellow lake is thrown down.

A moderately concentrated solution of morintannic acid mixed at the boiling heat with a dilute solution of *neutral lead-acetate*, and quickly filtered, deposits small, yellow laminar crystals containing, when dried at 110°, which temperature they sustain without alteration, 33.09 per cent. carbon, 2.00 hydrogen, and 45.76 lead-oxide, agreeing with the formula $\text{C}^{26}\text{H}^{18}\text{Pb}^2\text{O}^{12} \cdot \text{Pb}^2\text{H}^2\text{O}^2$, which requires 32.84 C, 2.10 H, and 46.00 PbO (Hlasiwetz and Pfaundler). Wagner found in the lead-salt dried at 100°, 32.01 per cent. C, 2.17 H, and 44.27 PbO, which agrees nearly with the formula $\text{C}^{26}\text{H}^{18}\text{Pb}^2\text{O}^{12} \cdot \text{Pb}^2\text{H}^2\text{O}^2 + \text{H}^2\text{O}$.

MOROXITE. A greenish-blue variety of apatite, found at Arendal in Norway, and Pargas in Finland.

MOROXYLIC ACID. A volatile crystalline acid, said by Klaproth to exist as a calcium-salt in the stems of the mulberry tree (*Morus alba*). Landerer found the same calcium-salt in the so-called *Lachrymæ Mori*, which exude from mulberry stems. (Handw. d. Chem. v. 142.)

MORPHETINE. A product of the oxidation of morphine (p. 1052).

MORPHINE, or MORPHIA. $\text{C}^9\text{H}^{10}\text{NO}^3$.—This alkaloid, the most important of the opium-bases, was known in an impure state, as *Magisterium opii*, in the seventeenth century; but it was not obtained as a well-defined organic base till 1816, when Sertürner published a series of important researches upon it (Gilb. Ann. iv. 61; lvi. 192; lix. 50). It has been further examined by Robiquet (Ann. Ch. Phys. [2] v. 275. li. 232); Pelletier and Caventou (*ibid.* xii. 122); Dumas and Pelletier (*ibid.* xxiv. 182); Lassaigne (*ibid.* xxv. 102); Dublane (*ibid.* xxvii. 84); Liebig (*ibid.* xlvii. 105; Ann. Ch. Pharm. xxvi. 41); Merck (Ann. Ch. Pharm. xviii. 79; xxi. 202; xxiv. 46); Regnault (Ann. Ch. Phys. [2] lxxviii. 131); Laurent (*ibid.* [3] xix. 361); Lefort (J. Pharm. [3] xl. 97); and Guibourt (*ibid.* xli. 97, 177). Good Smyrna opium generally contains from 10 to 15 per cent. morphine. Egyptian opium from 6.8 to 6.6 per cent.; East Indian from 6.3 to 7.7 per cent.

Preparation.—1. Opium is exhausted with cold water; the extract after evaporation to a syrup at a gentle heat, is heated while yet warm with a large excess of carbonate of sodium as long as ammonia continues to escape; the resulting precipitate is collected after twenty-four hours, and washed with cold water; and when the wash-water is no longer coloured, the precipitate is treated with alcohol of 85 per cent., again dried, and exhausted in the cold with very dilute acetic acid, care being taken not to add too much acid at once, and to wait till each portion is neutralised before adding more. The solution is then filtered, decolorised with animal charcoal, and precipitated by ammonia, care being taken to avoid an excess; and the precipitate, after being well-washed, is dissolved in boiling alcohol. The liquid on cooling deposits crystals of morphine, and an additional quantity may be obtained by concentrating the mother-liquors. (Merck.)

2. Twenty pts. of opium cut in slices are boiled in sixty pts. water for half an hour, or until all the slices are opened out; the liquid is then strained, and the residue is squeezed and again twice treated with fresh water in the same way. The united extracts are boiled down to half their bulk, then stirred into a boiling lime-lye composed of 3 pts. slaked lime and 40 pts. water; the liquid is boiled for a quarter of an hour,

and then strained; and the calcareous residue is pressed and again twice boiled in 50 pts. water. The whole of the calcareous liquors are now boiled down to 40 pts. and mixed at boiling heat with 2 pts. sal-ammoniac; the heat is kept up for an hour, or as long as ammonia is given off; the liquid is then allowed to cool; and after eight days the morphine, which separates in the form of brown granules, is collected; the mother-liquor yields another crop if further boiled down and left to itself. The product may be purified by washing in cold water, solution in hydrochloric acid, repeated boiling with excess of milk of lime, and precipitation with sal-ammoniac. (Mohr, Ann. Ch. Pharm. xxxv. 120.)

3. The process most generally employed is that of Robertson, modified by Robiquet and Gregory (Ann. Ch. Pharm. v. 87; vii. 261).—Opium is macerated in water of 38°, till all the soluble principles are extracted; the solution is evaporated with carbonate of calcium, which neutralises the free acids; and when the liquid is sufficiently concentrated, chloride of calcium is added, whereby a precipitate of meconate of calcium is formed, which carries down with it a considerable quantity of colouring matter. The opium bases remain in the solution as hydrochlorates, and the liquid, when again concentrated, first deposits more meconate of calcium, and afterwards crystals of hydrochlorate of morphine mixed with hydrochlorate of codeine. These salts are easily purified by repeated crystallisation, with addition of animal charcoal.

The two hydrochlorates are next dissolved in water and treated with ammonia, which precipitates the morphine, leaving the codeine dissolved. The morphine is finally purified by crystallisation from alcohol.

Morphine prepared by either of the preceding processes is often contaminated with narcotine, from which however it may be freed by either of the following processes:—1. By digestion in ether, which dissolves narcotine much more easily than morphine.—2. By dissolving the mixed bases in hydrochloric acid, evaporating to the crystallising point, and pressing the crystals, which consist entirely of hydrochlorate of morphine, the narcotine-salt remaining in the uncrystallisable mother-liquor.—3. By mixing the hydrochloric acid solution with common salt, which renders the liquid milky, and throws down the narcotine after some days in crystalline agglomerations; the morphine may then be precipitated by ammonia.—4. By pouring a weak solution of caustic potash into the dilute solution of the hydrochlorates; the morphine then dissolves in a slight excess of potash, while the narcotine is deposited as a curdy precipitate, which may be separated by filtration.

For a full account of the various methods used for the preparation and purification of morphine, see *Gucllin's Handbook*, xvi. 416–423.

Properties.—Morphine crystallises in colourless transparent prisms usually very short, belonging to the trimetric system. Observed combination: $\infty P : \infty P \infty : P \infty$. Angle $\infty P : \infty P = 127^\circ 30'$; $\infty P : P \infty = 116^\circ 20'$; $P \infty : P \infty = 132^\circ 20'$; $P \infty : P \infty = 95^\circ 20'$. Cleavage parallel to $\infty P \infty$. It is inodorous but has a persistently bitter taste, and is extremely poisonous, exerting a strong narcotic action. In small doses it is much used in medicine as a sedative.

Morphine is but very slightly soluble in cold water; boiling water dissolves about $\frac{1}{60}$ of it, depositing the greater part of it in the crystalline form as it cools. Cold alcohol dissolves but little of it; boiling alcohol a larger quantity. It is insoluble in ether, and may thus be easily separated from narcotine, which is dissolved by ether. Morphine is likewise insoluble in volatile oils. Aqueous alkalis, even lime-water, dissolve it readily; ammonia, however, but sparingly.

Morphine turns the plane of polarisation of a luminous ray to the left. In the state of concentrated solution in water acidulated with hydrochloric acid, its molecular rotatory power is expressed by $[\alpha] = -88.04$. It has likewise about the same amount of rotatory power when dissolved in alcohol.

The crystals of morphine melt when heated, giving off 5.94 per cent. (= 1 at.) water of crystallisation; at a high temperature they become carbonised.

The composition of morphine dried at 120° is expressed by the formula $C^{17}H^{19}NO^5$, as seen from the following results of analysis:

	Calculation.	Liebig.*		Regnault.†			Will.‡	Laurent.§

† Ann. Ch. Phys. lxxviii. 131.
§ Ibid. [3] xix. 360.

of opium-tincture, were probably nothing but impure morphine. (See *Gmelin's Hand-book*, xvi. 440.)

Reactions.—Morphine and its salts are very sensitive to the action of oxidising agents.

1. *Iodic acid* is reduced by morphine either free or combined, the liquid turning brown and emitting an odour of iodine. This reaction will indicate the presence of 1 pt. of morphine in 7000 pts. of liquid (Serullas). *Periodic acid* acts in the same manner. *Ammonia* deepens the colour of a solution of iodic acid and morphine (J. Lefert, *J. Pharm.* [3] xl. 97). When solid morphine or a morphine-salt is moistened with a solution of 1 pt. iodic acid in 15 pts. water, and a solution of 1 pt. starch in 400 pts. water is added, a blue colour is produced, by which $\frac{1}{300}$ th of a grain may be detected; if a drop of the starch-solution be previously evaporated with the morphine, the reaction will suffice for the detection of $\frac{1}{10,000}$ th of a grain. If a layer of very dilute ammonia be poured upon a solution of morphine mixed with iodic acid and starch, then, even if only $\frac{1}{20,000}$ pt. of morphine is present, two coloured rings will be formed at the surface of contact, the upper being blue, the lower brown; in more dilute solutions only the brown ring is produced. Other substances capable of reducing iodic acid may likewise produce the blue ring, but not the brown ring at the same time. (A. Dupré, *Chem. News*, viii. 267; *Jahresb.* 1863, p. 704.)

2. Morphine and its salts slowly reduce *nitrate of silver*.

3. *Chloride of gold* colours them blue, from reduction of the metal.

4. They reduce *permanganate of potassium*, which acquires a green colour

5. *Ferrie salts* impart to morphine and its solutions a blue colour, which however is not permanent, and is destroyed by excess of acid, by heat, or by contact with alcohol. This reaction is characteristic of morphine (Robinet). A solution of morphine in sulphuric acid previously heated is coloured deep red by ferric chloride, the colour changing after a while to dirty green. (Husemann, *Ann. Ch. Pharm.* cxxviii. 305.)

6. When sulphate of morphine mixed with dilute sulphuric acid is boiled with *peroxide of lead*, till the liquid is no longer precipitated by ammonia, the excess of sulphuric acid then removed by carbonate of lead, and the lead by sulphuretted hydrogen, the filtered liquid yields on evaporation a brown amorphous slightly bitter substance (*morphetine*), which reddens litmus, is soluble in water, sparingly soluble in strong alcohol, acquires a darker colour by contact with alkalis, and is not precipitated by acetate of lead. By continued action of the peroxide of lead, it is converted into a yellow deliquescent acid body.

7. *Nitric acid* communicates to morphine an orange-red colour gradually changing to yellow. In this reaction, an acid body is produced which when boiled with potash gives off a volatile oil. (Anderson, *Ann. Ch. Pharm.* lxxv. 80.)

8. Warm dilute *sulphuric acid* converts morphine into sulphomorphide.

9. Morphine dissolved in strong sulphuric acid containing a little *nitric acid* forms a violet-red solution (J. Erdmann, *Ann. Ch. Pharm.* cxx. 88). According to A. Husemann (*ibid.* cxxviii. 305), this reaction may be rendered much more certain and delicate by first dissolving the base in strong sulphuric acid, in the proportion of 0.002 to 0.004 grm. to 6 or 8 drops of the acid, and then adding a drop of nitric acid, whereupon, if the morphine-solution has been recently prepared, a rose-colour is produced, changing after a few seconds to yellow, then to greenish, and finally to brown. If a small quantity of water be added to the solution of the morphine in sulphuric acid, so that the mixture becomes hot, the colouring produced by the subsequent addition of nitric acid is of a much deeper carmine-red, and much more durable. If the solution be heated for a few minutes to 100°–150°, the addition of a drop of nitric acid produces, after cooling, a splendid deep violet colour, which gradually disappears from the centre outwards, passing through blood-red. If the temperature be raised above 150°, the liquid acquires of itself at a certain moment, a violet-rose colour; at still higher temperatures, a dirty green colour is produced. On adding a drop of nitric acid, after cooling, the liquid immediately turns red, without passing through violet. A solution of morphine in sulphuric acid, left to itself for 12 to 24 hours at ordinary temperatures, behaves as if it had been heated to 100°–150°.

Hypochlorite of sodium, *chlorine-water*, and *chlorate of potassium* exhibit with morphine the same reactions as nitric acid.

With regard to the sensibility of these reactions, Husemann finds that $\frac{1}{4}$ th of a milligramme of morphine is sufficient to produce a very bright carmine colour; $\frac{1}{10}$ th mgr. gives a very distinct reaction, and $\frac{1}{100}$ th mgr. still gives a perceptible tint after half a minute.

10. When *chlorine* is passed into water containing morphine in suspension, the morphine first acquires an orange colour, then dissolves completely; and if the passage of the chlorine be continued, the liquid turns yellow, and deposits flakes partly soluble in alcohol. (Pelletier.)

11. *Iodine* unites with morphine, forming the so-called iodomorphine (p. 1056).

Morphine heated to 200° with excess of hydrate of potassium, yields an alkaline distillate containing methylamine.

12. Morphine heated with the iodides of methyl and ethyl, yields hydriodate of methyl-morphine or of ethyl-morphine.

To detect the presence of morphine when mixed with animal matter, the substance is mixed with alumina, dried between 100° and 110°, then well pulverised and macerated in cold water acidulated with acetic acid. The solution treated with ammonia, deposits morphine, which may then be recognised by the characters above described, especially by its reactions with iodic acid, ferric salts, and nitric acid.

Estimation of Morphine in Opium.—15 grms. of opium cut in pieces are triturated with 60 grms. alcohol of 71 per cent.; the solution is strained through linen; and the residue, after being pressed, is again treated in the same way with 40 grms. alcohol. The alcoholic tincture mixed with 4 grms. of aqueous ammonia yields in 12 hours crystals of morphine and narcotine, which are collected, washed several times with water, and stirred up in the water; the crystals of morphine then sink to the bottom, while those of narcotine, being lighter, remain longer suspended and may be separated by decantation (Guillermont, J. Pharm. [3] xvi. 17). Riegel (Jahrb. pr. Pharm. xxiii. 202) removes the narcotine precipitated together with the morphine, by washing with ether or with chloroform. According to Reveil and Guibourt, the quantity of alcohol employed by Guillermont is not sufficient for the exhaustion of the opium, and 12 hours is not time enough for complete crystallisation. Guibourt therefore treats dry powdered opium, or the aqueous extract of opium, with alcohol, either warm or cold, allowing it in either case to stand in the cold for 24 hours, to permit the separation of the resin, the wax, and a portion of the narcotine. The tincture is drawn off with a pipette, the residue washed with alcohol, and the entire liquid precipitated by a slight excess of ammonia. After evaporation of the excess of ammonia, the morphine is allowed to crystallise out completely, then collected and washed with alcohol of 50 per cent., afterwards with alcohol of 40 per cent., and finally with ether. The extract prepared with cold water from 20 to 30 grms. of opium may also be redissolved in cold water; the solution precipitated by ammonia; and the precipitate collected after 36 hours, washed with cold water, then with alcohol of 40 or 50 per cent., and crystallised from boiling alcohol of 85 per cent. (Guibourt.)

F. F. Mayer (Am. J. Pharm. xxxv. 28) has given a volumetric process for estimating morphine and other alkaloids founded on their precipitability by *potassio-mercurio iodide*. The standard solution contains 13.546 grms. ($\frac{1}{10}$ at.) mercuric chloride and 49.8 grms. iodide of potassium in a litre; it is to be added to the solution to be tested (and not the contrary), and gives a perceptible precipitate with 1 pt. of morphine in 2500 pts. water. The formation of the precipitate is not interfered with by extractive matters, but is prevented by alcohol, ammonia, and acetic acid; to obtain greater accuracy, the excess of the precipitant may be estimated by a standard silver-solution. On the estimation of morphine, see further:—Fördes (Compt. rend. xlv. 1286; Kopp's Jahrb. 1857, 603); Meurein (J. Pharm. [3] xxiii. 176 and 262); L. Kieffer (Ann. Ch. Pharm. ciii. 271); A. Petit (J. Pharm. [3] xliii. 46); on an older process by Guillermont, see J. Pharm. xiv. 436.

On the detection and identification of morphine in cases of poisoning, see Lassaigne (Ann. Ch. Phys. [2] xxv. 102); Morner (J. Chim. xxiii. 12); Stas (J. Pharm. [3] xxii. 281); Flandin (Compt. rend. xxxvi. 517); Otto (Ann. Ch. Pharm. c. 46); v. Usler and J. Erdmann (Ann. Ch. Pharm. cxx. 121); J. Erdmann (Ann. Ch. Pharm. cxiii. 360); Helvig, *Das Mikroskop in der Toxicologie*, Mainz, 1864, p. 6; also the article, ALKALOIDS, in this Dictionary, i. 126.

Salts of Morphine.—Morphine dissolves easily even in dilute acids, forming perfectly neutral salts. It decomposes certain salts of lead, iron, copper, and mercury, combining with their acids. Most morphine-salts are crystallisable, inodorous, bitter, and very poisonous; they are soluble in water and in common alcohol, insoluble in ether, and in amyl alcohol. The solutions exhibit the reactions above described for morphine. According to Lassaigne and Feneulle, they deposit in the circuit of the voltaic battery, needles of morphine at the negative, and the acid at the positive pole. Their aqueous solutions mixed with ammonia, potash, soda, baryta, lime, or magnesia deposit morphine as a crystalline powder soluble in excess of the precipitant, except in the case of magnesia, difficultly soluble in excess of ammonia. According to Anderson (J. Pharm. [3] xiii. 143), the precipitate formed by ammonia is composed of microscopic rhombohedral crystals. Morphine-salts are precipitated by the neutral carbonates of the alkali-metals, and the precipitate is not soluble in excess. The acid carbonates of the alkali-metals precipitate only a portion of the morphine from neutral morphine-salts; and do not form any precipitate in cold acid solutions. Tartaric acid prevents the precipitation of morphine by the acid carbonates of the alkali-metals. (Oppermann, Compt. rend. xxi. 210.)

With *fluosilicic alcohol* (a saturated alcoholic solution of fluoride of silicon) morphine salts yield a crystalline precipitate; with *phosphomolybdic acid* (p. 1037), a pale yellow flocculent precipitate; they are also precipitated by *phosphotungstic acid* (a mixture of sodic tungstate and phosphoric acid), and by *phosphantimonio acid* (prepared by dropping pentachloride of antimony into aqueous phosphoric acid), not, however, when the solution is diluted 1000 times. (F. Schultze.)

Acetate of Morphine crystallises by spontaneous evaporation in tufts of needles very soluble in water, less soluble in alcohol. Its solution when evaporated by heat, is partly decomposed, giving off acetic acid and depositing crystals of morphine; by rapid evaporation, however, a varnish-like residue is obtained.

Aspartate of Morphine is a gummy mass containing shining crystals, very soluble in water.

Bromomercurate.—Resembles the *iodomercurate* (p. 1056) and is obtained in a similar manner. (Groves.)

Carbonate.—Morphine dissolves in water strongly charged with carbonic acid under pressure; and the solution cooled to a low temperature deposits carbonate of morphine in shortened prisms soluble in 4 pts. water, and decomposed by heat. Alkaline carbonates added to solutions of morphine throw down the free base.

Chlorate of Morphine forms long slender needles which decompose suddenly when heated, swelling up and carbonising.

Chlorhydrate or Hydrochlorate of Morphine, $C^{17}H^{19}NO^3.HCl.3H^2O$, crystallises in silky fibres, soluble in 20 pts. of cold water, in 1 pt. boiling water and still more soluble in alcohol.

The *chloromercurate*, $C^{17}H^{19}NO^3.HCl.2Hg^{2}Cl^2$, separates as a white crystalline precipitate, on mixing the solutions of its component salts, and the filtered liquid deposits, after a while, tufts of silky crystals, having the same composition. It is very sparingly soluble in water, alcohol and ether at ordinary temperatures, more soluble in boiling alcohol, which deposits it in the crystalline form. Hydrochloric acid dissolves it easily and deposits it by spontaneous evaporation in large crystals.

The *chloroplatinate*, $2(C^{17}H^{19}NO^3.HCl).PtCl^4$, is obtained as a yellow curdy precipitate; a certain quantity, however, remains dissolved and may be crystallised by evaporation at a gentle heat.

Croconate of Morphine is a dark yellow uncrystallisable bitter mass, soluble in water and in alcohol.

Cynoplatinate of Morphine, $2(C^{17}H^{19}NO^3.HCy^2).PtCy^2$.—Cyanide of platinum and potassium throws down from the aqueous solution of acetate of morphine, an amorphous curdy precipitate which soon becomes crystalline, causing the liquid to solidify into a brilliant white mass. It forms shining globules and funnel-shaped depressed discs consisting of small microscopic needles having a silky lustre when dry; becomes dark-yellow when heated and white again on cooling; melts partially at 160° to a brownish-yellow mass, and when further heated, swells up, gives off cyanogen, and burns with a sooty flame. It does not give off any water of crystallisation at 125° . (Schwartzbach, Chem. Centr. 1860, p. 304.)

Cyanurate of Morphine forms tufts of long needles mixed with crystals of cyanuric acid, even when morphine is present in excess. It is decomposed by recrystallisation, with formation of a white amorphous mass.

Fluorhydrate or Hydrofluatate of Morphine forms long colourless prisms sparingly soluble in water, insoluble in alcohol and ether.

Formate.—Small bitter prisms fusible and easily soluble in water.

Gallotannate.—Morphine-salts form with gallotannic acid, or tincture of galls, a white precipitate sparingly soluble in water, freely in acetic acid, gallic acid, and mineral acids, soluble also in alcohol.

Hippurate.—Transparent amorphous mass.

Hydroferricyanate.—Aqueous ferricyanide of potassium added to aqueous hydrochlorate of morphine forms, after a while, a crystalline easily decomposable precipitate (Dollfus); according to Neubauer, on the other hand, no precipitate is formed.—*Hydroferrocyanate*.—Hydroferrocyanic acid throws down from an alcoholic solution of morphine, after long standing, small, white, easily decomposable needles. (Dollfus.)

Iodhydrate or Hydriodate, $C^{17}H^{19}NO^3.HI.3H^2O$.—On mixing the solutions of 1 pt. iodide of potassium and 2 pts. acetate of morphine, small shining prisms are obtained, moderately soluble in water, and containing 28.8 per cent. iodine. (Winckler.)

Iodomercurates.—Iodomercurate of potassium throws down from aqueous sulphate or hydrochlorate of morphine, a pulverulent precipitate, which soon becomes gelatinous, and is insoluble in hydrochloric acid (v. Planta, Delffs). When morphine, mercuric chloride, and iodide of potassium are brought together in aqueous solution, a double salt, $C^{17}H^{19}NO^2.HgI^2$ [or $C^{17}H^{19}O^2.HI.Hg^2I^2$] is precipitated, sparingly soluble in water, more soluble in alcohol. It is crystallisable, free from water of crystallisation, not decomposed by dilute acids, even on boiling, or on addition of iodide of potassium; decomposed by caustic alkalis. (Groves, Chem. Soc. J. xi. 97.)

Kinate of Morphine is a transparent gum exhibiting traces of crystallisation.

Meconate of Morphine is uncrystallisable, very soluble in water and in alcohol; reddens ferric salts. This salt is contained in aqueous extract of opium.

Mellitate. $C^{17}H^{19}NO^2.C^4H^4O^4$.—The solution of morphine in hot concentrated aqueous mellitic acid soon deposits white, microscopic, needle-shaped crystals, which give off 2 per cent. of their weight at 110° . They are rather more soluble in cold than in hot water, freely in aqueous ammonia and potash, not in alcohol or in ether (Karmrodt, Ann. Ch. Pharm. lxxxi. 171). A *diabasic mellitate* appears to be formed, as a brown amorphous brittle mass, when cold aqueous mellitic acid is saturated with morphine, and the solution is evaporated. (Karmrodt.)

Nitrate of Morphine forms stellate rays soluble in $1\frac{1}{4}$ pt. water.

Pectate.—Recently precipitated pectic acid dissolves morphine, even in the cold, forming a thick gum which, after dilution with water, is thickened again by acids. (Braconnot.)

Phosphates.—Two phosphates of morphine appear to exist, the neutral salt crystallising in cubes, the acid salt in tufts. Phosphate of sodium added to solutions of morphine-salts, forms a crystalline precipitate very soluble in hydrochloric acid.

Picrate.—Picric acid forms with morphine-salts a sulphur-yellow pulverulent precipitate (v. Planta); no precipitate with the acetate. (Mereck.)

Pyrotartrate.—Fissured gum, soluble in water and in alcohol. (Arppe.)

Rhodizionate.—Ilyacinth-red; soluble, with reddish colour, in water and in alcohol. (Heller.)

Sulphates.—The *neutral salt* ($C^{17}H^{19}NO^2.H^2SO^4.10H^2O$), crystallises in tufts of colourless prisms, very soluble in water and having a silky lustre. They give off 11.87 per cent. (= 10 at.) water at 130° . There appears also to exist an *acid sulphate* of morphine, which is obtained by supersaturating the preceding salt with sulphuric acid, evaporating to dryness, and removing the excess of acid with ether.

When morphine is dissolved in dilute sulphuric acid, the solution evaporated till it begins to decompose, and cold water then poured into it, a substance called *sulphomorphide* is precipitated, having a constitution similar to that of an amide—that is to say, it may be regarded as produced from sulphate of morphine by elimination of water:

Sulphomorphide recently prepared is white and amorphous, but soon turns green even in sealed tubes. It dissolves in dilute acid and alkaline liquids. Strong acids and alkalis decompose it, forming a brown substance.

Sulphocyanate, $C^{17}H^{19}NO^2.CyHS$.—An alcoholic solution of morphine saturated with moderately concentrated sulphocyanic acid yields small, shining, limpid needles which melt at 100° .

Neutral solutions of morphine are not precipitated by sulphocyanate of potassium.

Tartrates. a. *Neutral,* $C^{17}H^{19}NO^2.C^4H^4O^6.3H^2O$.—When a solution of cream of tartar is neutralised with morphine, cream of tartar crystallises out first, then nodules of the morphine-salt, which must be removed in time, so as to keep them separate from the neutral tartrate of potassium which afterwards crystallises out. The salt may also be obtained by slow evaporation of an aqueous solution of tartaric acid neutralised with morphine. It forms nodular groups of crystals consisting of closely aggregated needles; effloresces on the surface at 20° ; loses on the average 6.64 per cent. water at 130° (3 at. = 6.8 per cent.), no more at 145° . Exhibits crystal-electricity (ii. 411) when heated to 130° or 140° , and retains it for an hour after cooling. Soluble in alcohol. The easily formed aqueous solution is not precipitated by caustic alkalis, alkaline carbonates, chloride of calcium, or ammonio-chloride of calcium. (Arppe, J. pr. Chem. iii. 332.)

b. *Acid salt,* $C^{17}H^{19}NO^2.C^4H^4O^6.\frac{1}{2}H^2O$.—Obtained by mixing the solution of the neutral salt with as much tartaric acid as it already contains. Crystallises by spontaneous evaporation in tufts of long rectangular flattened prisms. The air-dried salt gives off 1.99 per cent. ($\frac{1}{2}$ at.) water at 140° .

Urate of Morphine is obtained by boiling uric acid and morphine with water, and crystallises on cooling from a solution saturated at the boiling heat, in short brownish prisms which decompose when recrystallised. (Elderhorst.)

Valerate of Morphine forms fine large crystals having a fatty lustre and smelling strongly of valerianic acid. The crystals belong to the trimetric system, and are always hemihedral. Observed combination $\infty P. \infty P \infty. \tilde{P} \infty. \frac{P}{2}$. Angles measured

approximately, $\infty P : \infty P = 100^\circ$; $\tilde{P} : \tilde{P} \infty = 125^\circ 47'$; $\tilde{P} \infty : \frac{P}{2} = 148^\circ 28'$; $\frac{P}{2} : \infty P = 130^\circ$. (Pasteur, Ann. Ch. Phys. [3] xxxviii. 455.)

Derivatives of Morphine.

IODOMORPHINE, $4C^{17}H^{18}NO^3.3I^2$ (?).—A mixture of equal pts. of iodine and morphine dissolves completely at the boiling heat, forming a brown liquid, which by spontaneous evaporation deposits this compound in the form of a brown-red substance, the mother-liquor retaining hydriodate of morphine. The same compound is obtained by heating a solution of sulphate of morphine with iodine. It dissolves in acid and alkaline liquids when heated therein. It gives by analysis 35.34 per cent. iodine, the formula requiring 39.87 per cent.

Iodomorphine triturated with metallic mercury and a little alcohol gives up part of its iodine to the mercury, and is converted into a yellow amorphous mass, insoluble in cold water, sparingly soluble in boiling water, moderately soluble in alcohol, very soluble in alkaline liquids, insoluble in acids. Treated with nitrate of silver it yields a large quantity of iodide of silver. It melts when heated, giving off ammonia, without any trace of iodine. (Pelletier, Ann. Ch. Phys. lxiii. 185.)

METHYL AND ETHYL-MORPHINE. The iodides of ethyl and methyl act upon morphine, producing hydriodates of bases in which 1 at. of the hydrogen of morphine is replaced by ethyl or methyl.

Hydriodate of Methyl-morphine, $C^{17}H^{18}(CH^3)NO^3.HI.H^2O$, is very soluble in hot water, and is deposited on cooling in colourless rectangular needles, containing 4.04 per cent. water (= 1 at.). The solution treated with oxide of silver yields a brown amorphous mass, which is quickly attacked by iodide of methyl.

Hydriodate of Ethyl-morphine, $C^{17}H^{18}(C^2H^5)NO^3.HI.H^2O$, produced by heating morphine with iodide of ethyl and a small quantity of absolute alcohol, in a sealed tube, is very soluble in boiling water, and crystallises on cooling in slender needles, containing 1.98 per cent. water. It is sparingly soluble in absolute alcohol, more soluble in ordinary spirit, permanent in the air. The aqueous solution is not precipitated by potash or ammonia. Hence this salt is probably analogous to iodide of tetraethyl-ammonium, and the group $C^{17}H^{18}O^3$ in morphine appears to be equivalent to 3 at. hydrogen.

The hydriodate is decomposed by oxide of silver, yielding a very caustic liquid which when evaporated leaves a dark brown amorphous mass. (H. How, Chem. Soc. Qu. J. vi. 125.)

MORPHIUM. Syn. with MORPHINE.

MORPHOLITES. Earthy concretions found in Sweden, consisting of marl with between 47 and 49 per cent. carbonate of calcium; they have a slaty structure with laminae of unequal thickness and dissimilar colours. (See IMATRA STONES, p. 245.)

MORTAR. See *Ure's Dictionary of Arts, Manufactures, and Mines*, iii. 199.

MORVENITE. A brilliant variety of baryta-harmotome found at Strontian in Argyleshire (p. 13).

MOSAIC GOLD. Or *molu*. An alloy of copper and zinc in equal parts. (See COPPER, ALLOYS OF, ii. 49.)

MOSANDRITE. A silico-titanate of cerium, calcium, &c., found in radiate masses and imperfectly developed (monoclinic?) prisms, imbedded, together with leucophane, titaniferous iron, fluor-spar, &c., in the syenite forming the islet of Lammarskjäret, at the entrance of the Langesundfjord, near Brevig in Norway. It has a dark red-brown colour, vitreous to fatty lustre, and is usually more or less weathered. Hardness = 4. Specific gravity = 2.93 to 2.98. Contains 29.93 per cent. silica, 9.90 titanio anhydride, 26.56 oxides of cerium, lanthanum, and didymium, 1.83 ferric oxide, 0.75 magnesia, 19.07 lime, 0.52 potash, 2.87 soda, and 8.90 water (= 100.33). (Erdmann, Berz. Jahresb. xxi. 178.)

MOSS AGATE. See AGATE (i. 62).

MOTHER-LIQUOR or *Mother-water*. The portion of a mixed solution which remains after the less soluble salts or other bodies have crystallised out.

MOTHER-OF-PEARL. The hard silvery brilliant internal layer of several kinds of shells especially oyster shells, often exhibiting brilliant iridescence arising from the striated structure of its surface (see LIGHT, p. 608). It contains about 66 per cent. carbonate of calcium, 2.5 organic matter, and 31.5 water.

MOUNTAIN CORK or MOUNTAIN LEATHER. A variety of asbestos in which the fibres are so interlaced that the fibrous structure is not apparent.

MOUNTAIN BLUE. Syn. with AZURITE. (See CARBONATES, i. 783.)

MOUNTAIN GREEN. Syn. with MALACHITE. (See CARBONATES, i. 783.)

MOUNTAIN SOAP. See STRATITE.

MUCAMIDE. $C^6H^{12}N^2O^4 = \left(\begin{smallmatrix} H^1 \\ C^6H^4O^2 \\ H^1 \end{smallmatrix} \right)^1 O^4$ (Malaguti, Compt. rend. xxii.

854).—Produced by the action of ammonia on mucic ether. It is white, very slightly soluble in boiling water, and separates on cooling in microscopic crystals having the form of an octahedron with rhombic base, truncated on both summits, and looking like bevelled plates. It is tasteless and insoluble both in alcohol and in ether. Specific gravity 1.589 at 13.5°. Heated with water to 136°–140°, it is converted into mucate of ammonium:

A boiling solution of mucamide mixed with ammoniacal acetate of lead forms a precipitate of ammoniacal mucate of lead or *mucate of lead and plumbammonium*, $C^{12}H^{16}Pb^{10}(N^2H^4Pb^4)^{10}O^{16}.6H^2O$. A boiling saturated solution of mucamide forms with ammoniacal nitrate of silver a specular deposit of metallic silver.

Mucamide turns brown when heated a few degrees above 200°, and yields by dry distillation, water, dipyromucamide, a small quantity of pyromucic acid, carbonic anhydride, and carbonate of ammonium; the residue contains carbon and prussian cyanogen.

MUCIC ACID. $C^6H^{10}O^8 = \left(\begin{smallmatrix} H^1 \\ C^6H^4O^2 \\ H^1 \end{smallmatrix} \right)^1 O^4$.—This acid, isomeric with saccharic

acid, was discovered by Scheele in 1780, and has been examined chiefly by Laugier (Ann. Chim. xli. 79); Berzelius (*ibid.* xcii. 141; xciv. 6; xcv. 31); Malaguti (Ann. Ch. Phys. [2] lx. 195; lxiii. 86); Liebig and Pelouze (Ann. Ch. Pharm. xix. 258); Liebig (*ibid.* xxvi. 16) Hagen (Pogg. Ann. lxxi. 631); Johnson (Ann. Ch. Pharm. xciv. 226); and Schwanert (*ibid.* cxvi. 227); see also Gm. xi. 602; Gerh. ii. 143.

It is dibasic, and was formerly represented by the diatomic formula $\left(\begin{smallmatrix} C^6H^4O^2 \\ H^2 \end{smallmatrix} \right)^2 O^4$, but from its relation to the sugars, it is now regarded as derived from the hexatomic alcohol $C^6H^{14}O^6$, by the substitution of 2 at. O for 4 at. H, being accordingly represented by the formula $\left(\begin{smallmatrix} H^1 \\ C^6H^4O^2 \\ H^1 \end{smallmatrix} \right)^1 O^4$, the number of its basic hydrogen-atoms being, as in other

similar cases, equal to the number of oxygen-atoms which have entered into it by substitution. (Kekulé, *Lehrbuch*, ii. 237.)

Mucic acid is formed by the oxidation of milk-sugar, lactose or galactose (p. 1023), melitose, dulcitol, and various kinds of gum (viz. gum-arabic, tragacanth, &c.). It is prepared by heating milk-sugar with moderately dilute nitric acid. According to Guckelberger (Ann. Ch. Pharm. lxiv. 348), the best proportions are 1 pt. milk-sugar to 2 pts. nitric acid of specific gravity 1.42, the vessel being warmed till the reaction begins, then cooled, and afterwards gently warmed towards the end of the process. The product thus obtained, amounts to 60–65 per cent. of the milk-sugar employed. According to Pasteur, lactose treated with nitric acid yields twice as much mucic acid as milk-sugar. Gum-arabic may also be used for the preparation of mucic acid, 1 pt. of it being heated with 4 pts. nitric acid of specific gravity 1.36; but the acid thus obtained contains calcium-salts.

Crude mucic acid is purified by recrystallisation from boiling water, or better, especially if it has been prepared from gum, by dissolving it in ammonia, repeatedly crystallising the ammonium-salt from boiling water, and finally precipitating the mucic acid from the solution by nitric acid at the boiling heat.

Mucic acid crystallises in colourless tables with square base. It is sparingly soluble in cold water, soluble in 6 pts. of boiling water, and insoluble in alcohol. Sulphuric acid dissolves it with crimson colour.

Mucic acid boiled for some time with water undergoes an isomeric transformation, and is converted into an acid (paramucic acid) more soluble and more energetic

than mucic acid: its salts are also more soluble than the mucates, but their solutions in boiling water deposit mucates on cooling.

Mucic acid heated *per se* first melts, and then decomposes, yielding, among other products, pyromucic acid and carbonic anhydride:

When oxidised by boiling with *nitric acid*, it yields *racemic* and *oxalic acids* (Carlet). Distilled with *sulphuric acid* and *peroxide of manganese*, it gives off *formic acid*. By heating with *caustic potash*, it is converted into a mixture of *acetate* and *oxalate*:

Mucic acid is converted by *pentachloride of phosphorus* into a peculiar dibasic chlorinated acid, $C^6H^4Cl^2O^4$, which has not been thoroughly investigated, but evidently stands to mucic acid in the same relation as chloromaleic acid, $C^4H^2Cl^2O^4$, to tartaric acid, $C^4H^4O^6$ (Lies-Rodart, Ann. Ch. Pharm. c. 325). Mucic acid heated with *hydriodic acid* is converted into an acid having the composition of adipic acid, $C^6H^{10}O^4$. (Crum Brown, Ann. Ch. Pharm. cxxv. 19.)

Mucates. Mucic acid is dibasic. Its salts are for the most part neutral, of the form $C^6H^8M^2O^8$; but a few acid mucates of the alkali-metals are also known. The alkali-metal mucates are very soluble in water; the rest are mostly insoluble. The soluble mucates are decomposed by acids, with deposition of mucic acid. The mucates when heated give off the odour of caramel.

Mucates of Ammonium.—The *neutral salt*, $C^6H^8(NH^4)^2O^8$, is obtained by supersaturating the hot solution of the acid with ammonia, and repeatedly crystallising the salt which forms on cooling. The crystals are colourless flat four-sided prisms, which become soft and yellow at 220° , and between 220° and 210° are resolved into water, carbonic anhydride, carbonate of ammonium, pyromucic acid, and dipyromucamide, while small quantities of charcoal and parayanogen remain behind:

Possibly the pyromucic acid, formed as in the manner represented by the first equation, is converted into dipyromucamide by the action of the carbonate of ammonium formed at the same time.

Mucate of ammonium dissolves sparingly in cold, more freely in hot water: according to Malaguti, it is more soluble than the corresponding paramucate.

Acid mucate of ammonium, $C^6H^8(NH^4)O^8.H^2O$, prepared by neutralising 1 pt. of mucic acid with ammonia, and then adding an equal portion of the acid, crystallises in colourless needles or thin prisms which, after drying over oil of vitriol, give off 7.32 per cent. water (= 1 at.) at 100° . It is more soluble in water than the neutral salt, and when distilled yields the same products, together with a small quantity of a yellow oil, which is soluble in water, appears to boil below 100° , and quickly turns brown when exposed to the air.

The mucates of *barium*, *strontium*, and *calcium* are precipitated on adding mucate of ammonium to the chlorides. The *barium-salt* dried at 100° is $2C^6H^8Ba^2O^8.3H^2O$; the *calcium-salt* dried at 100° , has a similar composition.

Cupric mucate, $C^6H^8Cu^2O^8.H^2O$ (at 100°), is a bluish-white precipitate.

Ferrous mucate, $C^6H^8Fe^2O^8.2H^2O$ (at 100°), is a yellow powder precipitated by alkaline mucates from ferrous sulphate. It is permanent at ordinary temperatures, but takes fire between 150° and 160° .

Mucates of Lead.—A *hrabasia* (?) salt is obtained by precipitating basic acetate of lead with mucate of ammonium. The *neutral salt*, $C^6H^8Pb^2O^8.H^2O$, is obtained by precipitating nitrate, chloride, or neutral acetate of lead, with mucic acid or mucate of ammonium. It gives off its water at 130° .

Mucates of Potassium.—The *neutral salt* forms white granular crystals, containing $2C^6H^8K^2O^8.H^2O$, which remain unaltered at 100° , but turn yellow and give off 1 at. water at 150° . The salt dissolves in 8 pts. of hot water, and separates almost completely on cooling; it is insoluble in alcohol. The *acid salt*, prepared like the acid ammonium-salt, forms transparent crystals, which when dried in the air or at 100° contain $C^6H^8KO^8.H^2O$.

Mucate of Silver, $C^6H^8Ag^2O^8$, is obtained by precipitating nitrate of silver with mucic acid or a soluble mucate. It does not give off anything at 100° .

Mucates of Sodium.—The *neutral salt* forms large transparent crystals containing $2C^6H^8Na^2O^8.9H^2O$ which give off 8 at. water at 100° , and obstinately retain the last atom. The solution if rapidly boiled down deposits a white powder

containing $2\text{C}^*\text{H}^*\text{N}^*\text{O}^*\cdot\text{H}^*\text{O}$.—The acid sodium-salt, colourless shining prisms, containing $2\text{C}^*\text{H}^*\text{N}^*\text{O}^*\cdot 7\text{H}^*\text{O}$: they give off their water at 100° .

MUCIC ETHERS. *Amyl-mucic acid*, $\text{C}^*\text{H}^*(\text{C}^*\text{H}^*)^4\text{O}^*$, is produced by the action of sulphuric acid on a mixture of amyl alcohol and mucic acid. It is crystallisable, dissolves in boiling water and in alcohol.

Mucates of Ethyl. The neutral compound, $\text{C}^*\text{H}^*\text{O}^* = \text{C}^*\text{H}^*(\text{C}^*\text{H}^*)^2\text{O}^*$, commonly called *mucic ether*, is prepared by gently heating 1 pt. of mucic acid with 4 pts. of sulphuric acid till it turns black, then leaving it to cool, and adding 4 pts. of alcohol of specific gravity 0.814. The mixture left to itself for 24 hours solidifies in a mass, which must be shaken up with alcohol, thrown on a filter, washed with alcohol, and purified by repeated crystallisation from boiling alcohol.

Mucate of ethyl crystallises in transparent four-sided prisms, terminated by a single perpendicular face. It is insipid at first, but leaves a bitter aftertaste. It melts at 150° , and solidifies in a crystalline mass at 135° . At a higher temperature it is resolved into alcohol, water, carbonic anhydride, acetic acid, carbonated hydrogen, pyromucic acid, and charcoal. It is insoluble in ether, very soluble in boiling alcohol, very sparingly in cold alcohol; very soluble also in boiling water, which deposits it in well-defined crystals on cooling. The alkaline hydrates decompose it like other ethers: ammonia converts it into mucamide.

Ethylmucic acid or Mucovinic acid, $\text{C}^*\text{H}^*\text{O}^* = \text{C}^*\text{H}^*(\text{C}^*\text{H}^*)^2\text{O}^*$. In the preparation of neutral ethylic mucate, it sometimes happens that an aqueous solution of that compound not yet pure, gives off all at once a very decided alcoholic odour, and yields by evaporation a substance totally different in appearance from the neutral ether. It is purified by treatment with alcohol, which removes the neutral ether, and the residue is crystallised two or three times from water. The product is pure when its solution is no longer rendered turbid by ammonia.

Ethylmucic acid is white, of asbestos-like aspect, the form of its crystals being that of a right prism with rhombic base. It is moderately soluble in water, very slightly in alcohol. It has a pure acid taste, and melts at 190° , with decomposition. The melted mass assumes a vitreous aspect on cooling, but after a considerable time it softens and again becomes opaque.

Ethylmucate of ammonium, $\text{C}^*\text{H}^*(\text{NH}^*)\text{O}^*$, is very soluble, tasteless, and has a slight acid reaction. Its solution precipitates the salts of lead, silver, copper, barium, and strontium, very slightly those of calcium, and forms no precipitate with salts of zinc, magnesium, &c. All the precipitates are soluble in acetic acid.

When a solution of ethylmucic acid is boiled with oxide of silver, carbonic anhydride is evolved, a portion of the oxide is reduced, and a silver-compound is formed, which explodes when slightly heated.

Mucate of Methyl, $\text{C}^*\text{H}^*\text{O}^* = \text{C}^*\text{H}^*(\text{CH}^*)^2\text{O}^*$, is prepared like mucate of ethyl, and crystallises from water or alcohol in laminae, or in flattened six-sided prisms, colourless, non-volatile, and tasteless. It is very soluble in boiling water, very little in boiling alcohol. It decomposes at 163° without melting, and then changes to a black liquid, which swells up, and gives off gases containing carbon.

MUCEDINEÆ. From experiments on the growth of these fungi (*Asco-phora nigrans*), Ranlin (Compt. rend. lvii. 771) concludes that they require for their normal development the elements of phosphate and sulphate of ammonium and of the carbonates of potassium, magnesium and manganese, but that these elements are not all of equal value to them. If 20 grms. of the plant are produced in a given time in a liquid containing all the substances above mentioned, then in the same time there will be formed, in the absence of manganese, 6 grms.; of sulphur, 2 grms.; of potassium and magnesium, only 1 grm.; and in the absence of phosphorus, only half a gramme of the plant. Experiments in which these fungi were developed in a confined volume of air, showed that the nitrogen of the air was not essential to their growth. Similar results, so far as regards the mineral constituents, have been obtained with plants of higher orders, by G. Ville (Compt. rend. lvii. 270).

MUCILAGE. The gum of seeds, roots, &c. (See Gum, ii. 955.)

MUCIN. The name of one of the constituents of gluten (ii. 873); also of the chief constituent of animal mucus.

MUCUS. The normal secretion of mucous membranes. It is found in the respiratory, genito-urinary, digestive, &c. passages of animal bodies, mingled in certain situations with specific fluids furnished by special glands. It is very doubtful, however, whether the secretion ought to be considered as the same in all cases, whether in fact there is a one thing, mucus, modified by the addition of other matters from time to time, and not a different secretion altogether for each membrane or organ. When obtained in a state of approximate purity, mucus appears as an alkaline fluid of a very

peculiarly glairy, ropy nature. Under the microscope are seen, besides fatty and other granules, epithelial scales, varying in form and kind according to the nature of the membrane from which the mucus is obtained, and the so-called mucus-corpuscles, which differ in no essential respect from pus-corpuscles. These morphological elements vary exceedingly in number in different specimens, but are rarely, if ever, wholly absent.

Among the chemical constituents, the most important is *mucin*, a colloïd substance, existing in the liquid in an undissolved condition. To its presence is due the peculiar ropiness of the secretion.

Mucin is insoluble in water, and can be separated from it by filtration, though Scherer found on one occasion a mucus which was soluble in water and readily passed through the filter. Heat produces no coagulation; on the contrary, a real solution seems to be thereby effected. It may be precipitated by alcohol as a flocculent stringy mass, which on the subsequent addition of water, will swell up into its former colloïd state. Dilute acetic acid and mineral acids precipitate it; concentrated acids dissolve it readily; alkalis, especially when dilute, also dissolve it. From its solution in weak acids it may be precipitated by alkalis added with caution. Ferrocyanide of potassium produces no precipitate either in alkaline or acid solutions, except when a solution in strong acetic acid has been boiled. Tannic acid and basic acetate of lead throw it down from a faintly alkaline solution; the neutral acetate and mercuric chloride produce only a slight turbidity. Concentrated hot nitric acid colours it yellow. The addition of a large quantity of water generally coagulates it, probably owing to some of the solvent alkalis being thereby withdrawn. The difficulty of obtaining it pure detracts from the value of any elementary analysis. According to Scherer, 100 parts of it contain carbon 52.4, hydrogen 7.0, nitrogen 12.8, oxygen 27.8. It contains no sulphur, but gives 4 per cent. ash, consisting chiefly of phosphate of calcium and alkaline carbonates. Mucin is found not only in ordinary mucus, but also in synovia, in the contents of various cysts, in the pathological product known as "colloïd tissue" and in the unformed connective tissue of the umbilical cord and embryo.

Besides mucin, mucus contains a very small quantity of fat, various extractive matters, and salts. Among the latter are sulphates and phosphates of the alkali-metals, with earthy phosphates and especially alkaline chlorides. According to Berzelius, 100 parts of nasal mucus contain 93.37 water, 5.33 mucin and .56 alkaline chloride. Albumin is very often found in mucus, but may be regarded as an abnormal constituent. In certain pathological states, various forms of albumin are poured out in abundance on the surface of mucous membranes, as transudations. The secretion is also said at times to change from mucous into muco-purulent or purulent (see P's).

It has been thought that mucus was generated by the breaking-up of the epithelium of the mucous membranes. The want of relationship, however, between the number of such epithelium scales and the amount of mucin in any given quantity of mucus, and the presence of mucin in embryonal connective tissue, negative such an idea. Probably mucin is not secreted by the mucous membrane as such, but is developed on the free surfaces out of some unknown antecedents, perhaps in some such way as fibrin is formed out of its peculiar antecedents.

The great use of mucus seems to be to lubricate the passages where it is found. A ferment-action has been largely attributed to it. The mucus present in urine is said to be a chief cause of the change which urea speedily undergoes into carbonate of ammonium in exposed urine. The weak power of converting starch into sugar possessed by many mucus-bearing fluids, not containing saliva, has been supposed to be due to the mucus. This however is doubtful. The catalytic action of urine on starch certainly does not reside in its mucus (Cohnheim). In the mucus of the respiratory passages (sputa) during certain pathological states (bronchitis), the alkaline chlorides are much increased.

M. F.

MUDARIN. An extractive matter obtained from mudar-root, the root of *Asclepias gigantea*, L. (A. Duncan. Fontenelle, Ann. Ch. Pharm. xvii. 210.)

MUDESIC ACID. A product of the oxidation of mudesous acid.

MUDESIOUS ACID. $C^{12}H^{10}O^8$ (?)—An organic acid, which, in combination with alumina, forms the mineral called *Pigotite*, found coating the walls of certain granite caverns in Cornwall. Pigotite is brown; yields a yellowish powder; is insoluble in water and alcohol; gives off 27 per cent. water in drying; and decomposes at higher temperatures, giving off empyreumatic products, and leaving alumina mixed with charcoal. The acid separated from the alumina is dark-brown, permanent in the air, soluble in water, forms a deliquescent ammonium-salt, and gives brown precipitates with metallic salts. Nitric acid converts it into mudesic acid, a brownish-yellow substance, said to contain 2 at. oxygen more. Mudesous acid is supposed to have been formed from the remains of plants, its aqueous solution dissolving the alumina of the decomposed

granite as it percolated through the cavities. (Johnston, *Handw. d. Chem.* v. 406; vi. 502.)

A substance from Wicklow in Ireland, probably identical with Pigotite, has been examined by Apjohn (*Jahresb.* 1852, p. 903).

MULHOUSE BLUE. A blue dye, obtained by prolonged boiling of an alkaline solution of shellac with aniline-red. (Schaffner and Gros-Renaud, *Bull. Soc. Industr. de Mulhouse*, xxxi. 238; *Rép. Chim. appl.* iii. 273.)

MÜLLER'S GLASS, or *Hyalite*. A variety of *Opal*, (q. v.).

MULLERITE. Syn. with *SYLVANITE*.

MULLICITE. Syn. with *VIVIANITE*.

MULTIPLIER, or *Galvanometer* (see *ELECTRICITY*, ii. 443).

MUNJEET. *Rubia Munjista*.—This plant, also called *East Indian madder*, is extensively cultivated in India, its root being used as a dyestuff for producing colours similar to those obtained from ordinary madder. The colouring matters contained in it are, however, by no means identical with those of common madder; in fact, Stenhouse has shown that it contains no alizarin, but that its colouring matter is a mixture of purpurin and an orange-dye, called munjistin (see the next article). The colours which it produces are brighter than those of ordinary madder, but not so durable.

The tinctorial power of munjeet was first examined by Runge in 1835, who reported that it contained about twice as much available colouring matter as ordinary madder; but subsequent experiments, both by German and by English dyers, have shown that this result was incorrect, and that the colouring power of munjeet is actually much less than that of ordinary madder.

The actual amount of colouring matter in munjeet is indeed very nearly the same as in the best madder. Stenhouse finds that the garancin from munjeet has about half the tinctorial power of that made from the best madder, viz. Naples roots; these, however, yield only about 30 to 33 per cent. of garancin, whereas munjeet, according to the experiments of Mr. Higgin of Manchester, yields from 52 to 55 per cent.

The inferiority of munjeet as a dyestuff results from its containing only the comparatively feeble colouring matters purpurin and munjistin, only a small part of the latter being available, while its presence in large quantity appears to be positively injurious; so much so, indeed, that munjeet-garancin, freed by boiling water from the greater part of the munjistin which it contains, yields much richer shades with alumina-mordants than before. (Stenhouse, *Proc. Roy. Soc.* xiii. 148.)

MUNJISTIN. $C^{10}H^{10}O^3$. (Stenhouse, *Proc. Roy. Soc.* xii. 633; xiii. 86, 145.)—

An orange colouring matter contained, together with purpurin, in munjeet or East Indian madder. It is nearly related in composition to purpurin, $C^{10}H^{10}O^3$, and alizarin, $C^{12}H^{12}O^3$, differing from the former by 1 at. and from the latter by 2 at. carbon. It exists in munjeet in considerable quantity, and may be extracted by the following process:—

Each pound of munjeet in fine powder is boiled for four or five hours with 2 pounds of sulphate of aluminium and about 16 pounds of water, the operation being repeated two or three times; the red liquor thus obtained is strained through cloth filters while still very hot; and the clear filtrate is saturated with hydrochloric acid, whereby a bright-red precipitate is soon produced, which goes on increasing in quantity for about twelve hours if the liquid is left at rest. This precipitate is collected on cloth filters, and washed with cold water till the greater part of the acid is removed; then dried, pulverised, and digested in a percolator with boiling sulphide of carbon, which dissolves the crystallisable colouring principles of the munjeet, and leaves a considerable quantity of dark-coloured resinous matter. The excess of sulphide of carbon having been removed by distillation, the bright-red extract, consisting chiefly of a mixture of munjistin and purpurin, is repeatedly treated with moderate quantities of boiling water and filtered, the clear yellow filtrate consisting of a solution of munjistin, while nearly all the purpurin remains on the filter. The solution acidulated with hydrochloric or sulphuric acid deposits the munjistin in large yellow flocks, which are slightly washed on a filter with cold water, then dried by pressure, and dissolved in boiling spirits of wine, slightly acidulated with hydrochloric acid, to remove any adhering alumina. As the munjistin does not subside from cold alcoholic solutions, even when they are largely diluted with water, about three-fourths of the spirit must be distilled off, after which the munjistin is deposited in large yellow scales. By two or three crystallisations from spirit, in this manner, it may be rendered perfectly pure.

Munjistin may also be extracted directly from munjeet by boiling with water, acidulating the dark brownish-red filtrate with hydrochloric acid, and treating the precipitate as above; but the process above described yields a better product. The colouring

matter of munjeet may also be extracted by boiling solutions of alum; but sulphate of aluminium is better adapted for the purpose, as the alum, by its tendency to crystallise, greatly impedes the filtration of the liquids. E. Kepp's process with sulphurous acid (p. 749), is not applicable to munjeet.

Properties.—Munjistin crystallises from alcohol in golden-yellow plates of great brilliancy. It is but moderately soluble in cold, but dissolves pretty readily in boiling water, forming a bright-yellow solution, from which it is deposited in flocks on cooling. It dissolves to some extent in cold but more readily in boiling alcohol, and is not precipitated therefrom by water. It dissolves, with bright-red colour, in aqueous carbonate of sodium; with ammonia, it forms a red solution, having a slight tinge of brown; with caustic soda, it produces a rich crimson colour.

Munjistin, in some of its properties, bears considerable resemblance to the rubiacin of Schunck (madder-orange of Runge, p. 742); but according to Stokes (Proc. Roy. Soc. xii. 637), the two substances are perfectly distinguished by the colours of their solutions in carbonate of sodium, when a small quantity only of each is used, the solution of munjistin being red inclining to pinkish-orange, while that of rubiacin is claret-red; also by the absorption-bands which are seen on examining the spectra of these solutions (see LIGHT, p. 638); both present a single minimum in the spectrum; but while that of rubiacin extends only from about D to F, that of munjistin extends from a good way beyond D to some way beyond F. A further distinction is afforded by the characters of the fluorescent light of the ethereal solutions of these substances, that of rubiacin being orange-yellow, while that of munjistin is yellow inclining to green.

Munjistin sublimes more readily than either purpurin or alizarin, forming golden-yellow scales consisting of the unaltered substance. Neither sublimed munjistin, nor that obtained by crystallisation from alcohol and drying in a vacuum, loses any weight at 100°. When carefully heated in a tube it melts, and crystallises again on cooling. When strongly heated on platinum-foil, it readily takes fire, and burns away without residue.

Munjistin dissolves readily in cold sulphuric acid, forming a bright-orange solution which may be heated nearly to boiling without blackening or evolution of sulphurous acid, and on dilution with water, deposits the munjistin in yellow flocks apparently unaltered. By digestion with moderately strong nitric acid, it is converted (like alizarin and purpurin) into phthalic acid, $C^8H^4O^4$, together with a small quantity of oxalic acid.

Bromine-water added to a strong aqueous solution of munjistin throws down a pale-coloured flocculent precipitate, which when dissolved in hot alcohol, yields tufts of crystals, evidently a substitution-product.

Baryta-water forms a yellow precipitate with solutions of munjistin. Acetate of copper forms a brown precipitate very slightly soluble in acetic acid. Acetate of lead added either to the aqueous or to the alcoholic solution, throws down a bright-crimson precipitate, which when washed with alcohol and dried in a vacuum, contains, on the average, 34.8 per cent. carbon, 1.9 hydrogen, and 48.5 lead-oxide: agreeing nearly with the formula $Pb^{10}O_5.C^{10}H^{10}.Pb^{10}O_5$, analogous to that of the lead-compound of purpurin, $Pb^{10}O_5.C^{10}H^{10}.Pb^{10}O_5$, described by Wolff and Strecker (see PURPURIN).

Both the aqueous and alcoholic solutions of munjistin, when boiled with alumina, form a beautiful lake of a bright orange-colour, almost the whole of the munjistin being withdrawn from solution. This lake is soluble in a large excess of caustic soda, producing a fine crimson solution. Munjistin dyes cloth mordanted with alumina a bright orange; with iron mordant it yields a brownish-purple colour, and with Turkey-red mordant a pleasing deep orange. These colours are moderately permanent, and bear the application of bran and soap tolerably well.

When an ammoniacal solution of munjistin is exposed to the air, in a warm place, the munjistin is gradually but completely decomposed, the greater part being changed into a brown humus-like substance insoluble in ammonia; while the remainder forms a non-crystalline colouring substance, analogous to purpurein (the product formed in like manner from purpurin, *q. v.*), and capable of dyeing unmordanted cloth of a brownish-orange colour.

MUNTZ'S METAL. An alloy of copper and zinc used for sheathing ships, and for other purposes (see COPPER, ALLOYS OF, ii. 49).

MURCHISONITE. A yellowish-grey or flesh-red variety of felspar from Heavitree, near Exeter.

MUREXAN. *Dialurimide* (Laurent).—Discovered by Prout in 1818 (Ann. Ch. Phys. xi. 48), who called it *Purpuric acid*: further examined by Kodweiss (Pogg. Ann. xix. 12), and by Liebig and Wöhler (Ann. Ch. Pharm. xxvi. 327). It is formed by the decomposition of murexide by the stronger acids, sulphuretted hydrogen, or potash. It is obtained by adding sulphuric or hydrochloric acid to a boiling

solution of murexide in water or potash: the crystalline precipitate is purified by dissolving it in cold sulphuric acid, and precipitating by water; or by dissolving it in potash, and precipitating it by an acid. It is thus obtained as a heavy white powder, lustrous like uramil, infusible, tasteless, and does not redden litmus. It turns red in air containing ammonia. It is almost insoluble in cold water, requiring more than 10,000 pts. : insoluble in alcohol, ether, dilute sulphuric, hydrochloric, or phosphoric acid, or in aqueous, acetic, tartaric, or citric acid. It is soluble in cold strong sulphuric acid, and reprecipitated by water; also in aqueous alkalis, without neutralising them, forming solutions which are colourless when air is excluded.

Murexan is decomposed by *dry distillation*, yielding cyanic acid and other products. It is dissolved and decomposed by *chlorine-water*, without yielding cyanic acid. When heated with strong *nitric acid* it is dissolved with effervescence, giving off nitrous and carbonic anhydrides, and yielding on evaporation crystals of oxalate of murexan (Kodweiss). When heated with *sulphuric acid*, it evolves carbonic anhydride and a little nitrogen, and forms a brown solution, containing ammonia, and not precipitable by water. Its colourless solution in ammonia turns purple when exposed to the air, and on evaporation yields crystals of murexide :

The purple solution is decolorised by exposure to oxygen-gas, oxalurate of ammonium being formed.

Under certain circumstances murexan appears to combine with acids. It dissolves in warm dilute *nitric acid* without effervescence, and yields on evaporation small rhombohedra, which appear to be nitrate of murexan. When dissolved in *oxalic acid* containing a little nitric acid, or when heated with strong nitric acid, it yields crystals by evaporation, which, according to Kodweiss, are oxalate of murexan.

The composition of murexan is very variously stated. The analyses of Liebig and Wöhler, and of Kodweiss, yield very conflicting results: the former agrees tolerably with the formula $\text{C}^8\text{H}^8\text{N}^4\text{O}^8$, which is accordingly adopted by Liebig and Wöhler. Gerhardt (*Chim. org.* i. 1517) considers murexan as identical with dialuramide, $\text{C}^8\text{H}^8\text{N}^4\text{O}^8$: a view which is advocated by Beilstein (*Ann. Ch. Pharm.* cviii. 191), according to whose analyses murexan contains 29.54 per cent. nitrogen, which agrees tolerably with 29.38, the calculated percentage in $\text{C}^8\text{H}^8\text{N}^4\text{O}^8$. Gmelin adopts the formula $\text{C}^8\text{H}^8\text{N}^4\text{O}^8$, which gives percentages intermediate between the analyses, and leads to the simplest equations. Laurent (*Compt. rend.* xxxv. 629) adopts the same formula, and regards the compound as dialurimide— $\text{N}.\text{C}^8\text{H}^8\text{N}^4\text{O}^8.\text{H}$.

calc. L. and W.			L. and W.		Kodweiss.	calc. Gmelin.

F. T. C.

MUREXIDE. See PURPURATES.

MUREXOIN. A product formed by the joint action of air and ammonia on amalac acid, and crystallising from warm water or alcohol in vermilion-coloured four-sided prisms, two faces of which reflect light with gold-yellow colour. The solution of this compound resembles that of murexide, excepting that it is decolorised instead of being turned blue by potash, also by evaporation. When dried at 100°, it gives by analysis numbers agreeing approximately with the formula $\text{C}^8\text{H}^8\text{N}^4\text{O}^{10}$. (Rochleder, J. p. Chem. li. 398; Jahresh. 1850, p. 434.)

MURIACITE. Syn. with ANHYDRITE (i. 295).

MURIATIC ACID. The old name of chlorhydric or hydrochloric acid (i. 390).

MUROMONTITE. A variety of orthite (*q. v.*) from Baden near Marienberg in Saxony.

MUSA. The ripe fruit of the Banana (*Musa paradisiaca*), grown in Bengal, contains, according to Corenwinder (*Compt. rend.* lvii. 781), 73.9 per cent. water, 4.82 albumin, 0.2 cellulose, 0.63 fats, 19.66 cane-sugar and inverted sugar (together with organic acids, pectose, and traces of starch), 0.06 phosphoric anhydride, and 0.73 lime, alkalis, iron, chlorine, &c. The ash of the husk of the ripe fruit was found to contain 47.98 carbonate of potassium, 6.58 carbonate of sodium, 25.18 chloride of

potassium, 6.66 alkaline phosphates (with a little sulphate), 7.50 charcoal, 7.10 lime, silica, earthy phosphates, &c. (= 100).

In the milky juice of the flower-stem of the same plant, Cornille (J. Pharm. [3] xliii. 269) found 25.27 per cent. potash, 9.52 soda, 15.85 lime, 5.00 magnesia, 0.87 alumina, with a trace of ferric oxide, 6.30 chlorine, 0.96 sulphuric anhydride, 0.87 phosphoric anhydride, 0.81 silica, and 34.17 carbonic anhydride (calculated from the bases).

MUSCLE. See MUSCULAR TISSUE.

MUSCOVITE. Potash-mica. (See MICA, p. 1010.)

MUSCULAR TISSUE. A. *Striated muscles*.—*Voluntary Muscles*.—*Muscles of animal life*.—*Muscles taking part in energetic movements*.—These consist of parallel primitive bundles of fibres bound together with fatty and connective tissue, the latter affording gelatin, not proper to muscular tissue itself. Each fibre may be considered as a tube consisting of—1. A sheath or *sarcolemma*, resembling, physically and chemically, elastic tissue;—2. *Nuclei*, whose exact chemical composition is unknown;—3. The *muscle-substance* or *fluid* (semifluid) contents of the sheath, marked with the transverse striae;—4. *Granules*, &c., mostly fatty;—5. Terminations of nerves &c. (?)

The living fibre is contractile, and very extensible (slight but very perfect elasticity); its substance is transparent. When the nutrition of a muscle is arrested, contractility is lost, and the condition known as *rigor mortis* comes on. The fibre is then opaque, is shorter and thicker than during life, and has lost much of its extensibility. The peculiar rigidity thus brought about passes away as putrefactive decomposition sets in.

The rapidity with which *rigor mortis* appears in the muscles of an animal, after somatic death, depends upon a variety of circumstances. An apparently identical rigidity may be instantaneously brought about by plunging muscles in water or oil, at a temperature of 40° (for cold-blooded animals, 49°—50° for mammals, 53° for birds; Kühne, *Myolog. Untersuch.*), or by injecting into the blood-vessels various substances, such as chloroform (Küssmaul, Virchow Archiv. xiii. p. 289). *Rigor mortis* has been considered as a species of contraction,—“the last vital effort of the dying muscle,” or the natural condition into which a muscle falls, when no longer sustained by life (Radeliffé). It seems more probable, however, as will be seen below, that it is due to a spontaneous coagulation of the muscle-substance.

The reaction of the living fibre, when freed as far as possible from blood, is neutral or amphichromatic. After death, with the onset of *rigor mortis*, it becomes acid, and continues so until changed by ammoniacal compounds generated in putrefaction. The acid is probably formed first in the interior of the fibre, for the natural surface of the muscle remains neutral the longest; and if it be due to any process of oxidation, the oxygen must be furnished by the muscle-substance itself, since the presence of external oxygen is wholly unnecessary. The reaction cannot be attributed to the acid phosphate of potassium, for the mark on litmus is permanent, which in that case it would not be. It is generally supposed to be due to lactic (sarcolactic) acid. When *rigor* is artificially produced by a temperature of 40° (frogs), the reaction at the same time becomes acid. When muscles, however, are plunged into water at 75°, they coagulate immediately, with a distinctly alkaline reaction, and at intermediate degrees are neutral, with a tendency to acidity or alkalinity. The alkaline reaction at 75° is not due to any destruction of a temporarily formed acid, or to any neutralisation of it by the alkali set free by the coagulation of the albumin; for muscles which have once become acid remain so, even when immersed for some time in boiling water. So also muscles coagulated by being plunged into alcohol remain neutral. There seems, therefore, to be no causal connection between *rigor mortis* and the post-mortem acid reaction. (Du Bois-Reymond, *Moleschott. Untersuch.* 1860, p. i.)

Though *rigor mortis* may be considered as a sign of death, the injection of blood through the vessels of a rigid limb will remove rigidity and restore contractility. (Stannius, Brown-Sequard). Kühne, however (*op. cit.*), denies that any such revival can take place when rigidity and acidity have fairly set in. The rigidity nevertheless may be removed by an injection of chloride of sodium, and Kühne makes (*Untersuch. über Protoplasma*) the interesting observation that the acid reaction disappears at the same time; and Präyer (Central-blatt. med. wissensch. 1864, p. 769), states that if a blood-injection follow the chloride of sodium injection, contractility may be restored.

The *muscle-substance*, whose fluidity is indicated by the wave-like phenomena of its contractions, by its movement towards the negative pole during the passage of an electric current (Kühne), and by the behaviour of living parasites lodged within the *sarcolemma*, was supposed by Brücke, and has been shown by Kühne (*op. cit.*), to contain a body whose spontaneous coagulation brings about the rigidity and opacity of the dead fibre. If a frog be opened, a 1 per cent. solution of chloride of sodium driven through

the blood-vessels until all blood is removed, the muscles then rapidly chopped up and subjected to firm pressure, a liquid will be obtained, which in a short time sets into a firm coagulum, while the remaining fragments of muscle show a great lack of rigidity. In such an experiment, however, much of the muscle-substance will, through the treatment, be rendered rigid before the liquid can be expressed from it. In order to obtain an amount of coagulation sufficient to justify the idea that the rigidity is due to a coagulation of the muscle-substance itself, and not of any lymph or plasma bathing the fibres, muscles freed from blood by the injection of the (1 per cent.) solution of chloride of sodium are frozen, minutely divided, mixed with four times their volume of snow containing 1 per cent. of chloride of sodium, and the mass pulverized as far as possible. At -3° the mixture will become sufficiently liquid to be filtered through linen; at 0° it may be rapidly passed through filtering paper. The filtrate then appears as a slightly opalescent fluid, which, exposed to ordinary temperature, will speedily set into a coagulum so firm, that the containing vessel may be turned over without any fear of spilling the contents. At a temperature of 40° coagulation takes place instantaneously. On standing the coagulum contracts, after the fashion of a blood-clot, but shows a great tendency to the production of flocks and flakes, and leaves the surrounding liquid highly opalescent. Adopting the phraseology used in speaking of blood, the fluid parts of muscle may be described as forming a muscle-plasma, which separates into the muscle-clot and muscle-serum.

The act of coagulation may fairly be supposed to be, like that of blood, the union into an insoluble compound of two soluble factors. Kühne found that one of the factors of blood-coagulation, viz. globulin, increased and hastened the coagulation of muscle-plasma. The cause or determining circumstance of the coagulation is unknown.

Myosin (the name given by Kühne to the muscle-clot) is, when thoroughly washed, completely neutral, forms when wet a white mass of little transparency, when dry a yellow horny substance. It gives the usual protein reactions, and contains sulphur. It is insoluble in water, alcohol, and ether, exceedingly soluble in very dilute acids, and alkalis, and in solutions of neutral salts of all degrees of concentration. In a 10 per cent. solution of chloride of sodium it is especially soluble, and may by this means be extracted from muscles already coagulated. (Hence in brine there is always to be found a considerable quantity of it.) If such a solution in chloride of sodium be added drop by drop to distilled water, the myosin is precipitated in flakes or lumps, sometimes as little vesicles. The precipitate so formed is unaltered myosin, and is readily redissolved in the chloride of sodium solution. The precipitate obtained, however, by the neutralisation of dilute acid or alkaline solutions of myosin is no longer myosin; it has changed in character, is no longer soluble in the chloride of sodium solution, and exhibits the reactions of syntonin.

In muscle-serum (that is, muscle-plasma minus muscle-clot or myosin) Kühne recognises at least three forms of albumin:—

1. An albumin whose coagulation depends in great part on the degree of acidity possessed by the serum. If abundance of acid be present, coagulation will occur at a temperature so low as 30° . In this body Kühne recognises the mixture of potassic albuminate and sodic phosphate described by Rollett.

2. An albumin coagulating at 44° .

3. A large quantity of albumin coagulating at 75° . There are also in untouched muscle other forms coagulating at 90° . The first form had been previously recognised by Harless (Henle u. Meissner's Bericht, 1859, p. 471), and was regarded by him as the chief cause of rigor mortis. And even though the formation of myosin, which is quite independent of the formation of acid, be considered as the chief part of rigor mortis, yet the subsequent coagulation caused or favoured by the presence of the acid will undoubtedly increase that condition.

Before the researches of Kühne, muscle was considered to consist of a small quantity of albumin and of a large quantity of syntonin. Myosin is not the same thing as syntonin. Kühne contends that syntonin does not exist as such in the untouched muscle, but is an artificial product due to the action of the dilute acid on myosin and other albuminoid bodies. He attributes the rapidity of the solution of the muscle-substance to the conjoined action of pepsin (the presence of which in muscles has been shown by Brücke), and affirms that a formation of syntonin always precedes that of the peptones in every digestion of albumin. v. Wittich (Königsberg. med. Jahrb. iii. 210) also adopts the same view (see SYNTONIN). Hence muscle-fibrin or syntonin prepared by Liebig's method would be regarded as consisting of myosin and the albumin coagulating at 30° ; muscle-juice as a mixture of the other forms of albumin.

The *Heart* is singular in being an involuntary muscle, and yet being composed of striated fibres. It is remarkable for containing inosite, which is not found in other muscles. The alcoholic extract exhibits that excess over the watery extract which is

characteristic of muscles actively exercised. Its reaction is the same as that of other striated muscles. (Du Bois-Reymond.)

B. Non-striated, smooth muscles,—Involuntary muscles,—Muscles of organic life,—Muscles taking part in slow movements,—Contractile fibre-cells.—These consist of long spindle-shaped cells, or riband-like fibres, marked with peculiar rod-like nuclei, and bound together with connective tissue, bloodvessels, nerves, &c. Greater difficulty is met with in the analysis of this variety, since the fibres are but seldom found in large isolated masses, and are much mixed up with other tissues. The "juice" is less in quantity and often mixed with other fluids. Lehmann found the reaction of the juice of the muscular coat of the pig's stomach distinctly acid, that of the middle coat of arteries feebly acid, that of *Tunica Dartos* neutral (*Lehrbuch*, iii. p. 62). Du Bois-Reymond however, found the muscles of the gizzard of fowls and pigeons always faintly alkaline after death, as also the muscular coat of intestines and arteries of oxen. Schultze too (*Ann. Ch. Pharm.* lxxi. p. 277) had previously observed the same reaction. Yet Siegmund (*Verh. phys. med. Gesellsch. Würzburg*, iii. 50) discovered in the uterine muscles, acetic, formic, and lactic acids. From the smooth muscles a substance apparently identical with the syntonin of striated muscles may be obtained; and since the former exhibit rigor mortis, they also probably contain a form of albumin capable of coagulating spontaneously. Schultze (*op. cit.*) obtained from the smooth muscles of the middle coat of arteries a large quantity (7 to 21 per cent. of total dry matter) of a substance which he believed to be casein. Creatine is found in small quantities. The proportion of potash to soda is much less than in striated muscles—38 : 62 in the muscles of the stomach, 42 : 58 in the middle coat of the arteries. This would seem to imply a great mixture of blood-serum.

C. Muscles of Invertebrata.—These are in some classes striated (e.g. *Articulata*); in others, non-striated (e.g. *Mollusca*), and yet more closely allied with the striated than with the non-striated variety of vertebrata.

They probably agree in their main chemical feature with other muscles. Bernstein (*Centralblatt für med. Wissensch.* 1863, p. 437) found the muscles of the crab neutral or faintly alkaline when living, but becoming acid with the onset of rigor mortis. He also obtained a spontaneous coagulation of the expressed muscle-juice. In bivalve muscles he found the foot neutral, the adductors always acid. Both gave a spontaneously coagulating juice.

Valenciennes and Frémy (*Ann. Ch. Phys.* i. 129) found oleophosphoric acid to replace the acid phosphate of potassium in the muscles of the crab, and in molluscs they ascertained the absence of creatine and creatinine and the presence of taurine.

D. Protoplasmata,—Sarcode.—The bodies of many of the lower animals consist in great part of a semifluid substance, capable of peculiar movements. A similar matter is also found in vegetable cells and in the cells of certain parts of animals (cornea, connective tissue). From the researches of Schultze (*Das Protoplasma*) and Kühne (*op. cit.*) it appears that this protoplasm is contractile, spontaneously coagulating, and exhibits other reactions which bespeak for it a close alliance with muscle-substance.

Metamorphosis of Muscular Tissue.—The chemical changes taking place in the living muscle, though most imperfectly known, may be generally described as those of oxidation. Living muscles consume oxygen and produce carbonic acid (Liebig, *G. Müller's Archiv.* 1850, p. 409; Matteucci, *Compt. rend.* 1856, i. 14; Valentin, *Archiv. Physiol. Heilk. N.F.* i. p. 285); the excretion of carbonic acid is continued when the muscle is placed in hydrogen-gas. Products of oxidation of nitrogenous material are always present in muscle—creatine, creatinine, inosic acid (proteic acid), hypoxanthine, taurine, leucine, &c.

On comparing the chemical composition of muscles at rest with that of muscles at work, it is found that by the act of contraction, the substances soluble in alcohol are increased and those soluble in water diminished (Helmholtz); the carbonic acid exhaled and the oxygen consumed are increased, the proportion of carbonic acid to oxygen being at the same time also increased (Matteucci, Valentin, *op. cit.*; Sezelkow, *Zeitsch. nat. Med.* xvii. p. 106); the substances given up to the blood are increased, (Cl. Bernard, *Med. Times and Gaz.* 1861, ii. p. 26); creatinine is increased partly at the expense of creatine. Heidenhain (*Mechanische Leistung, &c., bei der Muskelthätigkeit*) finds the amount of acid produced to be proportional to that of the actual energy liberated during the contraction (Sarkow, *Virchow's Archiv.* 28, p. 544). A muscle when tetanised becomes acid from a development of lactic acid (Du Bois-Reymond, *op. cit.*). It is uncertain whether this acid is a product newly formed or a permanent constituent temporarily increased in amount. Borszewow (*Würgb. natur. Wissensch. Zeitsch.* ii. p. 66) finds no lactic acid in living hearts; Folwaczny

(Henle u. Meissner, 1861, p. 295), however, finds it. With regard to creatine, Horszczow (*op. cit.*) believes that it is formed at the expense of creatinine, while Neubauer (*Zeitsch. analyt. Chem.* 1863, p. 22) regards creatinine as an artificial production and no natural constituent of muscle.

The position of the carbo-hydrates in muscle is a very uncertain one. In the muscles of the embryo, glycogen is found in abundance (Bernard, *Journal de Physiolog.* ii. p. 39; Rouget, *ibid.* p. 333); in the muscles of adults, occasionally. (McDonnell, *Nat. Hist. Rev.* iii. 538.)

Besides inosite, which exists in the muscles of the heart, Meissner (Henle u. Meissner, 1861, p. 295) has found in the muscles of the system, a fermentable sugar (not arising from food), which presents, as he thinks, some differences from hepatic sugar, and is probably due to muscular metamorphosis. Harley (*Brit. For. Med. Chir. Review*, 1857) and Chauveau (*Gaz. Med.* No. 23), however, find reason to believe in the destruction of sugar in the systemic capillaries (and therefore in part at least in the muscles).

Since exercise, *ceteris paribus*, increases rigor mortis, it might be inferred that one at least of the factors of myosis was developed during muscular metamorphosis. In the generally adopted views, the nitrogenous muscle-substance, the 'plastic' element, is supposed to supply by its conversion the force of muscular movements. Others (Traube) have maintained that the hydrocarbons and carbo-hydrates (of blood and muscle) are to be regarded as the main source of power. M. F.

MUSENA BARK. This bark, used in Abyssinia as an anthelmintic, contains, according to Thiel (*J. Pharm.* [3] xlii. 176), a sharp-tasting colloidal substance called musenin, soluble in water and in alcohol, insoluble in ether.

MUSENITE. Cobalt-pyrites from Müsen, near Siegen, in Prussia (i. 1050).

MUSK. *Musc. Moschus.*—An odoriferous resinous substance contained in a bag near the navel of the male musk-deer, a small animal inhabiting Tonquin and Thibet. Musk occurs in commerce in brownish clots, often mixed with hair, sand, fat, and resins. It has a bitter taste, a persistent odour, is very inflammable, and partially soluble in water and in alcohol. According to an analysis by Geiger and Reimann, it contains in 100 parts, 1.1 parts fat, 4.0 cholesterolin, 5.0 bitter resin, 7.5 alcoholic extract (lactic acid-salts), 36.5 salts soluble in water (potash and ammonia, combined with a peculiar animal matter), 45.5 ammonia combined with lactic acid and water, and 0.4 sand. (Pelouze et Frémy, *Traité*, vi. 240. See also *Ure's Dict. of Arts, &c.*, iii. 211.)

MUSSEL-SHELLS. See SHELLS.

MUSSITE. Syn. with diopside or white angite (see ANGITE, i. 475).

MUSSONITE. Syn. with PARISITE.

MUST. The juice of the grape, expressed for making wine, but not yet fermented (see WINE). The same term is also applied to the freshly-expressed juice of apple, and pears, previous to conversion into cider and perry by fermentation.

MUSTARD. The seeds of black and white mustard (*Sinapis nigra* and *S. alba*), when ground and sifted, furnish the *flour of mustard* used as a condiment.

The seed of white mustard yields an ash containing 25.78 per cent. potash, 0.33 soda, 19.10 lime, 5.90 magnesia, 0.30 ferric oxide, 2.19 sulphuric anhydride, 1.31 silica, 44.97 phosphoric anhydride, and a trace of chloride of sodium: 100 parts of the fresh seeds yielded 4.07, and 100 parts of the dried seeds 4.45 parts ash; 100 parts of the air-dried seeds were found to contain 8.50 parts moisture and 1.212 parts sulphur. (Way and Ogston, *Jahresh.* 1850, Table B, p. 660.)

MUSTARD, OILS OF. *a. Fixed Oils.* White mustard-seed yields by pressure about 36 per cent. of a yellow nearly inodorous oil, which has a specific gravity of 0.9145 at 15°, and is not solidified by cold. When saponified with soda, it yields glycerin and a soap which is perfectly soluble in water, and when decomposed by hydrochloric acid, yields a solid crystalline acid, called erucic acid (ii. 501), and an oily acid having nearly the composition of oleic acid.

Black mustard-seed yields 18 per cent. of an oil similar to the preceding, having a density of 0.917°, but solidifying at temperatures below 0°. According to Darby (*Ann. Ch. Pharm.* lxi. 1), it yields by saponification, stearic acid, erucic acid, and an oily acid.

β. Volatile Oil. When the flour of black mustard, after being freed by pressure from the fixed oil, is moistened with water, left to itself for several hours, and then distilled with water, it yields a very pungent volatile oil, having the properties and composition of sulphocyanate of allyl, $C^H^4NS = \frac{CN}{C^H^4}$ (8). It is especially distinguished by its behaviour with ammonia, with which it immediately unites, forming crystalline thioisinnamine or sulphocyanate of allyl-ammonium, $H^4C^H^4N.CNS$ (see SULPHOCYANIC ETHERS).

This volatile oil does not pre-exist in the seed of black mustard, but is produced from myronic acid (p. 1073) contained in the seed, under the influence of water and a peculiar ferment called myrosin (p. 1075), likewise existing therein. Accordingly, it is not produced unless the mustard-flour is macerated with water for some time previous to distillation. Its formation is likewise prevented by drying the flour at a high temperature, or by heating it with alcohol or acids, as by these processes the myrosin is rendered inactive.

The quantity of volatile oil obtained from black mustard is but small, amounting to only 0.2 per cent. according to Boutron and Robiquet, 0.55 per cent. according to Aschoff, and 0.6 per cent. according to Wittstock.

White mustard does not yield any volatile oil, because it does not contain myronic acid.

MYCLOCLONE. Syn. with CEREBROTE (i. 830).

MYCODERMA. A generic name of the fungi (also called *Torvulae*), which, according to Pasteur and others, are essential to the processes of vinous and acetous fermentation. See Pasteur (Bull. Soc. Chim. de Paris, 1861, p. 94; Jahresb. 1861, p. 726; Compt. rend. lv. 28; Jahresb. 1862, p. 475); also the articles FERMENTATION, VINEGAR, and WINE, in this Dictionary.

MYCOMELIC ACID. *Alloxenide* (Laurent), *Alloxanamide* (Gerhardt), $C_8H_7N^2O^{11}.4H^2O$. (Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 304.)—When aqueous alloxan is heated gently with ammonia, it becomes yellow, and on cooling deposits a yellow transparent jelly of mycomelate of ammonium (see ALLOXAN, i. 137), from the hot aqueous solution of which salt sulphuric acid precipitates mycomelic acid. When freshly precipitated, it is transparent and gelatinous; but when washed and dried it is a loose yellow powder, which reddens litmus. It is scarcely soluble in cold water, more soluble in hot; insoluble in alcohol and ether; soluble in alkalis without forming crystallisable salts: its solution in potash is decomposed by boiling, with evolution of ammonia. It decomposes alkaline carbonates.

It is a monobasic acid. The only mycomelate known, beside the ammonium-salt, is the silver-salt, which is precipitated in yellow flakes when the ammonium-salt is added to nitrate of silver.

According to Liebig and Wöhler's analysis, the acid retains its $\frac{1}{2}$ atom of water when dried at 100° . Gerhardt (*Traité*, i. 514) regards it as alloxanamide (alloxan + $2NH^3 - 2H^2O$); Laurent (Compt. rend. xxxv. 629), as alloxanide (alloxanic acid + $2NH^3 - 3H^2O$).

According to Hlasiwetz (Ann. Ch. Pharm. ciii. 211), mycomelic acid is formed when uric acid is heated with water to $180-190^\circ$ in a closed vessel. F. T. C.

MYCOSE or TREHALOSE. $C^{12}H^{22}O^{11}$.—Wiggers in 1833 (Ann. Ch. Pharm. i. 173), observed in ergot of rye a peculiar kind of sugar, which was more exactly investigated in 1857 by Mitscherlich (*ibid.* cvi. 15), who designated it as mycose. Berthelot in the same year (Ann. Ch. Phys. [3] liii. 232, lv. 272, 291), obtained from trehala-manna, the produce of a species of *Echinops*, growing in the East, a sugar which he called trehalose, and at first regarded as different from mycose; but on further examination he was led to infer that the two are identical. (See *Gmelin's Handbook*, xv. 299–301.)

Mycose is obtained from ergot of rye by precipitating the aqueous extract of the fungus with basic acetate of lead, removing the lead from the filtrate by sulphydric acid, evaporating to a syrup, and leaving the liquid to crystallise. Trehalose is obtained from trehala-manna by exhaustion with boiling alcohol.

Mycose (trehalose) forms shining rhombic crystals, containing $C^{12}H^{22}O^{11}.2H^2O$, which melt when quickly heated to 109° ; but if slowly heated give off their water even below 100° . It has a strongly saccharine taste, dissolves easily in water and in boiling alcohol, but is insoluble in ether. The aqueous solution is dextro-rotatory. For trehalose, Berthelot found $[\alpha] = +199^\circ$ (for $C^{12}H^{22}O^{11}.2H^2O$); the specific rotatory power of mycose is, according to Mitscherlich, $[\alpha] = +192.5^\circ$.

By several hours boiling with dilute sulphuric acid, it is converted into dextro-glucose. With strong nitric acid it forms a detonating nitro-compound; heated with dilute nitric acid it yields oxalic acid. In contact with yeast it passes slowly and imperfectly into alcoholic fermentation. It is not altered by boiling with alkalis, and does not reduce cuprous oxide from alkaline cupric solutions. Heated with acetic or butyric acid, it yields saccharides, not distinguishable from those which are formed in like manner from dextro-glucose (ii. 854, 859).

MYELIN. A kind of kaolin, found at Rochlitz, of a yellowish or reddish colour, and containing, according to Kersten, 37.62 per cent. silver, 60.50 alumina, 0.82 magnesia, 0.63 manganic oxide, and a trace of ferric oxide.

The name myelin is also applied by Kirchow and Beneke (Ann. Ch. Pharm.

xxii. 249) to a peculiar fatty substance obtained by evaporating the alcoholic extract of hard-boiled yolk of egg, brain-substance, crystalline lenses, and other animal tissues. This substance—which is especially characterised by shooting out into peculiar spiral threads, or loops, when immersed in water or in a solution of sugar—is found, according to Beneke, in some of the lower animals (e.g. in *Helix Pomatia*, p. 140), and likewise in plants, viz. in young chlorophyll, in some flower-stalks, in certain seeds, especially in peas, and always accompanied by cholesterol. (Jahresb. 1862, p. 507.)

MYRICA-TALLOW. *Myrtle-wax*.—A solid fat, obtained by pressing the berries of *Myrica cerifera* (or *M. cordifolia*, John) with water. It is pale-green, translucent, brittle, and friable in the cold; of splintery fracture, less extensible when warm than beeswax; has an aromatic taste and odour. Specific gravity 1.005 (Moore, Sill. Am. J. [2] xxxiii. 113). Melts at 47° to 49° (Moore). When purified by treatment with boiling water and cold alcohol, it melts at 47.5° , and contains 74.03 per cent. C, 12.07 H, and 13.70 O (Lewy, Ann. Ch. Phys. [3] xiii. 448). It contains a large quantity of palmitic and a small quantity of myristic acid, for the most part in the free state, but to a smaller extent combined with glycerin; no oleic nor any volatile acid. (Moore.)

It dissolves in 20 pts. of hot alcohol, a portion (palmitin, according to Moore) remaining, however, undissolved, and on cooling $\frac{2}{3}$ separates out; the solution, formed with aid of heat, solidifies on cooling, and when perfectly cold is no longer precipitable by water. It is nearly insoluble in cold ether, but dissolves in 4 pts. of boiling ether, the solution, as it cools, depositing the greater part of the tallow without colour, and itself retaining a fine green colour. Cold oil of turpentine softens, and hot oil of turpentine dissolves $\frac{1}{2}$ pt. of it, the solution on cooling depositing white opaque granules. It likewise dissolves easily in fixed oils.

MYRICIN. (Brodie, Ann. Ch. Pharm. lxxi. 244).—The portion of beeswax which is insoluble in boiling alcohol. It is prepared by exhausting beeswax with boiling alcohol till the alcoholic liquid no longer gives a precipitate with acetate of lead. The myricin thus obtained melts at 61° , and has a faint waxy odour. It consists chiefly of palmitate of myricyl, $C^{32}H^{52}O_2 = C^{32}H^{50}(C^{20}H^{39})O_2$; and by dissolving it in ether, and leaving the solution to evaporate, the palmitate of myricyl is obtained in light plumose crystals, melting at 71.5° or 72° , and easily saponified by potash, especially in alcoholic solution, yielding palmitic acid and hydrate of myricyl. Crude myricin yields, by saponification, the same products, together with small quantities of another acid, and a neutral substance resembling hydrate of ceryl (i. 838). Crude myricin yields by dry distillation a number of fatty acids, of which palmitic acid forms the largest portion, together with solid and liquid hydrocarbons. (See MELNER, p. 868).

MYRICYL, HYDRATE OF. *Melissic alcohol*, *Melisin*, $C^{32}H^{52}O = \frac{C^{32}H^{50}O}{H} \cdot O$. (Brodie, Phil. Trans. 1848; Ann. Ch. Pharm. lxxi. 144).—This compound, which is the highest known alcohol of the series, $C^{32}H^{52}O$, is obtained by the action of melting potash upon myricin. On dissolving the product in water, precipitating the milky liquid, which contains the alcohol in suspension, with chloride of barium, exhausting the precipitate with ether, and leaving the solution to evaporate, hydrate of myricyl is deposited, and may be purified by crystallising it from ether, till it melts at 85° . A good mode of purification also is to exhaust the precipitate with boiling alcohol, and dissolve the substance which is deposited from the alcohol in rock-oil or rectified, coal-tar oil.

The mother-liquor then retains in solution a small quantity of another substance which melts at 72° and gives by analysis the same numbers as hydrate of myricyl. Brodie supposes it to be an alcohol of similar constitution. When treated with potash-line it yields an acid containing $C^{32}H^{50}O$. (?)

Hydrate of myricyl is a crystalline substance having a silky lustre. It contains, according to Brodie's analysis, 82.02–82.77 per cent. C, and 13.97–14.25 H. (calc. 83.19 C, 14.15 H, and 3.66 O.)

When subjected to dry distillation it partly sublimes unaltered, and is partly resolved into water and a solid hydrocarbon (melene, p. 868). Heated with potash-line it gives off hydrogen, and is converted into melissate of potassium:

With strong sulphuric acid it forms acid sulphate of myricyl. Chlorine converts it into a resinous body (*chloromelal*), which gives by analysis numbers corresponding to the formula $C^{32}H^{48}Cl^{14}O$.

MYRISTIC ACID. $C^{22}H^{42}O_2 = \frac{C^{22}H^{40}}{H} \cdot O$. (Playfair, Phil. Mag. [3] xviii. 202; Ann. Ch. Pharm. xxxvii. 153.—Heintz, Pogg. Ann. lxxxvii. 267; xc. 187; xcii. 429 and 588.—Summary of the Results, J. pr. Chem. lxi. 1.—Uricoschea, Ann.

Ch. Pharm. xc. 369.—Schlippe, *ibid.* cv. 1.—Oudemanns, J. pr. Chem. lxxxi. 356 and 367.—Gm. xvi. 209).

This acid was discovered by Playfair, and obtained pure by Heintz. It occurs, as myristin (myristate of glyceryl), in nutmeg-butter (Playfair), in otoba-wax (Uricoechea), in dika-bread (ii. 330), amounting to more than one-half of the fatty acids contained therein; also in small quantity, together with many other fatty acids, in cocoanut-oil (Gorgeu, Ann. Ch. Pharm. lxvi. 314), in common butter (Heintz); in croton-oil (Schlippe); and in combination with ethal, or an analogous body, in spermaceti (Heintz). According to Heintz and Scharling, it may be produced artificially by heating ethal with potash-lime; but its formation in this way is doubtless due to the presence of methal or myristic alcohol (p. 1072) in the ethal employed.

Preparation. a. From *Spermaceti*.—When the fatty acids obtained, together with ethal, by the saponification of spermaceti, as described under LAURIC ACID, (p. 474), are dissolved in alcohol, a mixture of palmitic and stearic acids crystallises on cooling, while a portion of both these, and the whole of the myristic and lauric acids, remain in solution. By fractional precipitation with acetate of magnesium (at last, in presence of excess of ammonia) the alcoholic solution is again divided into two parts, the stearic, palmitic, and a portion of the myristic acid being thrown down as magnesium-salts, while the lauric acid and the rest of the myristic acid remain in solution.

Treatment of the precipitated magnesium-salts.—The magnesia is separated from the fatty acids by boiling them with dilute hydrochloric acid; the melting-point of each portion of acid so obtained is determined; and those portions which melt nearly at the same temperature, and do not differ essentially in their mode of solidifying, are mixed together. When, now, the mixture of acids is repeatedly crystallised from alcohol, and the melting-point of the crystallising portion determined every time, several successive crops of crystals are obtained from each mixture. These are to be considered pure:—1. When their melting-point remains the same after repeated crystallisation; 2. When they solidify, on cooling, in crystalline scales; and 3. When, on fractional precipitation of their alcoholic solutions with acetate of magnesium, portions having one and the same melting-point are obtained. The several portions of the same acid show also, when pure, the same melting-point after being mixed together as when separate. Sometimes, especially in the preparation of myristic acid, it is necessary to subject the single crystallisations anew to fractional precipitation, and to repeat the above treatment and examination of the magnesium-salts thus obtained. (Heintz, Pogg. Ann. xcli. 429.)

In this way Heintz obtained, by the first precipitation with acetate of magnesium, nineteen magnesium-salts, from each of which he separated the acids. He mixed together the first six portions of acid, the melting-points of which varied from 42.7° to 45°, allowed them to separate from alcohol, and repeated the crystallisation fourteen times; but even the last crystallisation proved to be a mixture of palmitic and stearic acids, and in no case was a pure acid obtained. By precipitating the mother-liquor from the first nine crystallisations in seven portions with acetate of magnesium, he succeeded in obtaining, from the first, second, and third portions, after eight or nine times repeated crystallisation, pure, or nearly pure, palmitic acid. The fourth and fifth portions, yielded by seven times repeated, the sixth and seventh by three times repeated crystallisation, myristic acid melting at 53.7, which showed the above signs of purity. Of the remaining acids of the nineteen magnesium-salts, the seventh and eighth portions did not yield a pure acid by repeated crystallisation, but were recognised as mixtures of palmitic and myristic acids. The 9—17th portions were mixed together. The part which first separated from an alcoholic solution did not yield a pure acid on repeated crystallisation; after returning it to the mother-liquor, therefore, a portion of the acids present was precipitated by the addition of a little acetate of barium. The filtrate mixed with water deposited, in the cold, crystals melting at 53.8°, which yielded, on recrystallisation, pure myristic acid. The acid separated from the eighteenth and nineteenth portions, proved, after three crystallisations, to be also myristic acid. The quantity of myristic acid obtained from spermaceti is but small.

β. From *common butter*.—The mixture of acids obtained by saponifying butter and decomposing the soap, is freed from volatile acids by boiling with water, and from oleic acid by treating the lead-salt with ether, afterwards dissolved in alcohol and allowed to crystallise. After removing by recrystallisation as much of the acid present as can be obtained with a melting-point of 56° or 57° (containing palmitic and stearic acids), the collected alcoholic mother-liquors are subjected to fractional precipitation with acetate of magnesium; the myristic acid is thrown down in the last portions of the precipitate, and may be obtained therefrom by recrystallisation, removing, if necessary, the substances at first precipitable by acetate of barium. (Heintz.)

γ. The acids obtained by the saponification of *dika-fat* yield myristic acid on repeated

crystallisation from alcohol, while a second portion of the acid, together with lauric acid, remains in solution. This latter portion may be recovered by precipitating the solution in several parts with acetate of magnesium, separating the magnesia, and crystallising the separate portions of acid until the melting point rises to 53.8° . (Oudemans.)

5. From *Myristin*. Playfair saponifies the myristin of nutmeg-butter with strong caustic potash; washes the soap repeatedly with solution of common salt; and afterwards decomposes the hot aqueous solution with hydrochloric acid. The acid, which separates as a colourless oil, solidifying on cooling, when freed from all traces of hydrochloric acid by washing with water, yields, on repeated crystallisation from alcohol, Playfair's myristic acid, having a melting-point of 49.8° (impure, therefore, and contaminated with an acid containing a smaller proportion of carbon). (Heintz.)

6. By saponifying *eloba fat*, acids are obtained, from an alcoholic solution of which acetate of magnesium precipitates only, or chiefly, myristic acid, while oleic acid remains in solution. (Uricoechea.)

Properties.—Myristic acid forms white, shining, crystalline laminae, resembling palmitic acid. It has an acid reaction, is perfectly insoluble in water, but dissolves easily in hot alcohol, crystallising on cooling; it is perfectly insoluble in ether. It melts at 53.8° , and solidifies on cooling in crystalline scales. (Heintz.)

TABLE of the Melting-points of Mixtures of Lauric and Myristic Acids, according to Heintz.

A mixture of—		Melts at	Solidifies at	Mode of solidifying.
Myristic acid.	Lauric acid.			
90	10	51.8°	47.3°	Crystalline scales.
80	20	49.6	44.5	Very fine crystals, not distinguishable as either needles or scales.
70	30	43.7	39	Ditto ditto
60	40	43	39	Uncrystallised, with isolated lustrous spots.
50	50	37.4	35.7	Large crystalline laminae.
40	60	36.7	33.5	Uncrystallised, with isolated lustrous spots.
30	70	35.1	32.3	Uncrystallised, wavy.
20	80	38.5	33	Ditto ditto
10	90	41.3	36	Crystalline needles.

It will be observed that when the lauric acid amounts to 40 per cent. or more, the melting-point of the mixture lies below that of either constituent. This is generally the case in mixtures of fatty acids, when the quantity of the more fusible constituent exceeds a certain portion of the whole.

Decompositions.—1. Myristic acid subjected to dry distillation, is partly decomposed and partly volatilised unaltered.—2. On boiling with nitric acid, a part is converted into soluble products, with evolution of red vapours, the remaining undissolved portion behaving like unchanged myristic acid (Playfair).—3. By the dry distillation of the calcium-salt, myristone is produced (Overbeck).—4. A mixture of myristate and formate of calcium yields a repulsive-smelling oil, which deposits a small quantity of a solid product. This last, purified by recrystallisation, forms small, white, crystalline scales containing a larger proportion of carbon and hydrogen than would be contained in myristic aldehyde (Limprecht, Ann. Ch. Pharm. xvii. 371).—5. Myristate of potassium heated with oxychloride of phosphorus, yields myristic anhydride; with chloride of benzoyl, benzo-myristic anhydride. (Chiozza and Malerba.)

MYRISTATES.—Myristic acid is monobasic, the general formula of the myristates being $C^{17}H^{33}MO^2$ or $C^{17}H^{31}M^2O^4$, according as they contain mono- or di-atomic metals. The myristates of the alkali-metals are not decomposed by water (like the stearates) with formation of acid salts. (Playfair.)

Myristate of Barium, $C^{17}H^{31}Ba^2O^4$, is obtained from chloride of barium and myristate of potassium by double decomposition (Playfair). Heintz precipitates hot alcoholic myristic acid with a hot concentrated aqueous solution of acetate of barium, and washes the precipitate with weak alcohol and hot water. Oudemans precipitates the ammonia acid with chloride of barium. It is a very light crystalline powder, consisting of thin microscopic nacreous laminae. It is very slightly soluble in water and alcohol, and decomposes before melting.

Myristate of Copper, $C^{22}H^{34}Cu^2O^4$, is obtained by precipitation, as a very light, loose, bluish-green powder, consisting of microscopic needles. It becomes deeper-coloured when heated above 100° , and cakes together before melting.

Myristate of Lead, $C^{22}H^{34}Pb^2O^4$, obtained by precipitation, is a white, loose, amorphous powder which melts at 100° — 120° , and solidifies on cooling, in a white, opaque, amorphous mass (Heintz). An *aceto-myristate of lead*, $C^4H^8Pb^2O^4 \cdot 4C^{22}H^{34}Pb^2O^4$, is obtained as a heavy white powder, insoluble in water, by heating myristin for several days with basic acetate of lead.

Myristate of Magnesium. $C^{22}H^{34}Mg^2O^4$.—Myristic acid, to which ammonia and sal-ammoniac have been added, is precipitated by sulphate of magnesium, and the precipitate washed with water. Very light powder, consisting of microscopic needles; becoming transparent at 140° , semi-fluid at 150° , and decomposing at a higher temperature. The salt dried in the air contains 9.54 per cent. water (3 at. = 10.15 per cent. H^2O). (Heintz.)

Myristate of Potassium. $C^{11}H^{22}KO^2$.—Myristic acid is digested with concentrated aqueous carbonate of potassium; the product evaporated to dryness, and the myristate of potassium extracted by absolute alcohol. It forms a white crystalline soap, easily soluble in water and in alcohol, insoluble in ether. (Playfair.)

Myristate of Silver, $C^{11}H^{22}AgO^2$, is obtained by double decomposition, from the sodium-salt and nitrate of silver, as a white, light, amorphous powder, turning slightly grey when exposed to light. It decomposes above 100° , without melting (Heintz); dissolves in aqueous ammonia, and forms, by spontaneous evaporation, large transparent crystals. (Playfair.)

Myristate of Sodium, $C^{11}H^{22}NaO^2$.—A boiling aqueous solution of carbonate of sodium, quite free from sulphate and chloride, is added in excess to boiling alcoholic myristic acid, and the mixture is evaporated completely to dryness in the water-bath. The residue is then extracted with boiling absolute alcohol, and filtered boiling hot. The filtrate, which solidifies to a jelly on cooling, is liquefied by warming, and mixed with water in the proportion of one-eighth of the alcohol employed, whereby a mother-liquor is formed which takes up any foreign salts present. On again solidifying, the salt is collected on linen and strongly pressed. (Heintz.)

MYRISTIC ALCOHOL. *Methal*. $C^{11}H^{20}O = \begin{matrix} C^{11}H^{20} \\ H \end{matrix} \left. \vphantom{\begin{matrix} C^{11}H^{20} \\ H \end{matrix}} \right\} O$.—This alcohol is supposed to exist together with cetylic alcohol or ethal, $C^{18}H^{36}O$, and others of the same series, in commercial spermaceti. When this substance is saponified, salts of stearic, palmitic, myristic, and lauric acids are obtained, together with crude ethal. Now when the latter is recrystallised from alcohol, pure ethal or cetylic alcohol (i. 841), crystallises whilst the homologous compounds, *stethal* $C^{26}H^{52}O$, *methal* $C^{11}H^{20}O$, and *lethal* $C^{12}H^{22}O$, remain in smaller quantity in the mother-liquors, inasmuch as the alcohols obtained from these mother-liquors (after the removal of the admixed fatty acids by repeated treatment with alcoholic potash and addition of water), yield, when heated with potash-lime to 275° — 280° , as long as hydrogen continues to escape, stearic, palmitic, myristic, and lauric acids. (Heintz, *Ann. Ch. Pharm.* xcii. 299; xevii. 271; *J. pr. Chem.* lxxvi. 19.)

MYRISTIC ANHYDRIDE. $C^{22}H^{40}O^3 = (C^{11}H^{20}O)^2 \cdot O$. (Chiozza and Mulerba, *Gerh. Traité*, ii. 789.)—Obtained, like other anhydrides of the same series, by the action of oxychloride of phosphorus on myristate of potassium. It is a fatty substance, which scarcely exhibits any crystalline texture. Its melting point is a few degrees lower than that of myristic acid. When slightly heated, it gives off vapours having a disagreeable odour. It is but slowly saponified by boiling caustic potash.

MYRISTIC ETHERS. *a. Myristate of Ethyl*, $C^{11}H^{22}(C^2H^5)O^2$.—Dry hydrochloric acid gas is passed into a hot solution of myristic acid in absolute alcohol, and the oil which separates on cooling is washed repeatedly with cold, and afterwards dissolved in a small quantity of warm alcohol. The layer of oil again formed on cooling, after being separated from the alcohol and cooled, deposits large, hard, very easily fusible crystals, from which the mother-liquor is to be decanted (Heintz). The specific gravity of myristic ether is 0.864 (Playfair). It dissolves easily in hot alcohol, and in ether.

B. Myristate of Glyceryl. Myricin. $C^{33}H^{56}O^6 = \begin{matrix} (C^{11}H^{20})^3 \\ (C^{11}H^{20}O)^3 \end{matrix} \left. \vphantom{\begin{matrix} (C^{11}H^{20})^3 \\ (C^{11}H^{20}O)^3 \end{matrix}} \right\} O^2$. (Playfair, *loc. cit.*)—When nutmegs, after exposure to the vapour of boiling water, are pressed between hot iron plates, a fatty matter called nutmeg-butter is separated, consisting of an oily liquid, which has not been examined, and a solid crystallisable fat, which is myristin. To separate the latter, the crude fat is digested with alcohol of ordinary

strength; the myristin, which floats on the surface of the liquid, is dissolved in boiling ether; and the crystals which separate on cooling are pressed between bibulous paper, then redissolved, and submitted to alternate pressure and crystallisation till they melt constantly at 31°. (Playfair.)

Myristin thus prepared is crystalline, and has a silky lustre. It is soluble in all proportions in boiling ether, less soluble in boiling alcohol, insoluble in water. By dry distillation it yields acrolein and a fatty acid. Digested in the water-bath with a solution of basic acetate of lead, it yields insoluble myristate of lead and a solution of glycerin.

Myristin contains, according to Playfair's analysis, 75.51—74.15 per cent. C, and 12.22—12.36 H, numbers agreeing nearly with the formula $C^{18}H^{32}O^{12}$ (calc. 74.51 C, 12.22 H, and 13.27 O), according to which myristin contains the elements of 4 at. myristic acid and 1 at. glycerin minus 7 at. water:

Such a constitution is, however, not very probably, no corresponding example of it being found among glycerides of well-known constitution. The above formula $C^{18}H^{32}O^4$, proposed by Weltzien, requiring 74.82 per cent. carbon and 11.91 hydrogen, agrees satisfactorily with the results of Playfair's analyses.

The fat or wax of the fruit of *Myristica officinalis*, and that of *M. schifera*, possess properties similar to those of nutmeg-butter.

MYRISTICA. A genus of plants, including the nutmeg (*Myristica moschata*), the fruit and seeds of several species of which yield solid fats or waxes. *Bichuhya-wax* is obtained from *Myristica Bichuhya*; *Ocaba-wax* from *M. Ocaba* or *M. schifera*, *Otoba-wax*, or *Otobite*, from *M. Otoba* (see WAX). The seeds and arillus (mace) of *M. moschata* also yield volatile oils by distillation with water. (See MACE, p. 740; and NUTMEG.)

MYRISTICIN. The camphor or stereoptene of volatile oil of nutmeg. (See NUTMEG.)

MYRISTIN. See MYRISTIC ETHERS.

MYRISTO-BENZOIC ANHYDRIDE. *Myristate of Benzoyl* or *Benzoate of Myristyl*, $C^{18}H^{32}O^8 = C^{18}H^{32}O_2(C^{18}H^{32}O_2)$. (Chiozza and Mulert, loc. cit.)—Produced by the action of chloride of benzoyl on myristate of potassium. Crystallises in laminae having a silky lustre and agreeable odour. Melts at 38°; solidifies at 36°. Not very soluble in ether.

MYRISTONE. $C^{18}H^{34}O = C^{18}H^{32}O.C^{18}H^{32}$. (Overbeck, Pogg. Ann. lxxxvi. 591.)—A product obtained by distilling myristate of calcium by small portions and at a gradually increasing temperature. It is purified by repeated crystallisation from boiling alcohol, and decolorised if necessary by animal charcoal.

Myristone forms colourless nacreous scales, inodorous and tasteless; they become electrical by friction. It melts at 75°, and solidifies in a radiated mass on cooling. It gave by analysis 81.81 per cent. C, and 14.07—13.95 H, whence Overbeck deduces the formula $C^{18}H^{34}O$ (calc. 81.96 C, 13.65 H). Gerhardt suggested the formula above given (calc. 82.23 C, 13.7 H, 4.07 O), representing the compounds as the acetone of myristic acid.

MYRISTYL HYDRIDE OF. $C^{18}H^{30} = C^{18}H^{28}.H$.—This alcoholic hydride, more properly called hydride of tetradecetyl, is contained, together with many other hydrides of the same series, in American petroleum. It boils between 230° and 240°. (See PETROLEUM and TETRADECATYL.)

MYRONIC ACID. $C^{18}H^{16}NS^2O^{10}$ (from *μύρον*, a sweet-smelling ointment).—An acid occurring in the form of a potassium-salt in the seed of black mustard, and giving rise, by its reaction with myrosin, to the production of the volatile oil of black mustard (sulphocyanate of allyl). It was discovered by Bussy (J. Pharm. xvi. 39); and its existence, which was afterwards called in question by Thielau (Vierteljahrsschr. pr. Pharm. vii. 161), has been fully confirmed by the experiments of Ludwig and Lange (Zeitschr. Chem. Pharm. 1860, pp. 430 and 577) and of Will and Körner (Ann. Ch. Pharm. cxxv. 267; Jahresb. 1863, p. 495). According to Winckler (Jahresb. 1849, p. 436), myronate of potassium likewise exists in horse-radish.

Preparation of the Potassium-salt.—Two pounds of black mustard-seed pulverised but not freed from fixed oil by pressure, are boiled with 2½ to 3 pounds of alcohol of 80 to 85 per cent. in a glass flask placed in a water-bath till about half a pound of the alcohol has passed off; the powder is then pressed, and the residue is subjected to the same treatment. The press-cake (weighing from 660 to 670 grms.), after being well-dried and pulverised, is next macerated for about twelve hours with 3 pts. of cold water; the liquid is removed by decantation and pressure; the residue is again treated with 2

pts. water; the watery extracts are evaporated to a syrup, with addition of carbonate of barium (carbonate of lead would give rise to the formation of sulphide of lead); the syrup is boiled with 3 or 4 pounds of alcohol of 85 per cent.; and the undissolved residue is treated in the same manner with 2 pounds of alcohol. The united alcoholic extracts are filtered after standing for 24 hours; the alcohol is distilled off, and the clear residue left to crystallise in shallow dishes. Lastly, the crystalline mass which separates after a few days is stirred up to a thin pulp with alcohol of 75 per cent. then strongly pressed between linen cloths, and the nearly white cake thus obtained is repeatedly crystallised from alcohol of 84 to 90 per cent. Two pounds of mustard-seed thus treated yield, on the average, from 5 to 6 grms. of myronate of potassium. The portion remaining in the mother-liquors may be used for the preparation of cyanide of allyl (Will and Körner). This mode of preparation, and the similar method adopted by Ludwig and Lange, do not differ in any essential particular from that originally given by Bussy.

Myronic acid may be obtained from the potassium-salt, either by mixing the aqueous solutions of 100 pts. of this salt and 38 pts. tartaric acid, evaporating to a certain extent, and extracting the myronic acid with alcohol; or better, by converting the potassium-salt into a barium-salt, and precipitating its aqueous solution with an equivalent quantity of sulphuric acid. The colourless aqueous acid thus obtained leaves on evaporation an inodorous, bitter and sour, uncrystallisable syrup, which reddens litmus strongly, dissolves in alcohol, but is not perceptibly soluble in ether. It decomposes when more strongly heated, yielding various volatile products. Its dilute solution, when boiled for some time, gives off sulphuric acid. With an aqueous solution of *myrosin* it yields sulphocyanate of allyl. (Bussy.)

The myronates are inodorous and likewise yield sulphocyanate of allyl with aqueous *myrosin*. They are all, even the barium-, lead-, and silver-salts, soluble in water. The ammonium-, barium-, potassium- and sodium-salts are crystallisable. (Bussy.)

Myronate of Barium, $C^{10}H^{18}BaNS^2O^{10}$, obtained by decomposing the solution of the potassium-salt with tartaric acid and absolute alcohol, and digesting the resulting aqueous myronic acid with carbonate of barium, crystallises in easily soluble plates which become opaque and milk-white on exposure to the air, and are decomposed by heat, giving off oil of mustard and leaving sulphate of barium. (Will and Körner.)

Myronate of Potassium, $C^{10}H^{18}KNS^2O^{10}$, crystallises from alcohol in silky needles grouped like crystals of wavellite; from water, in short, transparent glassy prisms of rhombic character. It has a cooling bitter taste, dissolves very easily in water, with difficulty in dilute alcohol, is nearly insoluble in absolute alcohol, and quite insoluble in ether, benzene, and chloroform. The solutions are neutral and do not act on polarised light. The salt is anhydrous and contains the elements of oil of mustard, glucose and acid sulphate of potassium, into which products it is easily decomposed:

The dilute aqueous solution mixed with *myrosin*, or with a recently prepared aqueous extract of white mustard, becomes turbid in a short time, acquiring an acid reaction, and giving off the odour of oil of mustard. The solution then contains sulphuric acid and dextroglucose; the turbidity arises from free sulphur mixed with an insoluble organic substance probably formed from the *myrosin* (Will and Körner). Somewhat similar results of the decomposition of myronate of potassium have been obtained by Ludwig and Lange, who however assign to it the improbable formula $C^{72}H^{10}KNS^2O^{19}$. Myronate of potassium is not decomposed by emulsion, or an extract of sweet almonds, or by yeast or saliva.

When myronate of potassium is heated to boiling with a small quantity of *baryta-water*, a precipitate of barytic sulphate is formed, with copious evolution of mustard-oil. The same precipitate, containing half the sulphur in the original salt, is likewise formed when the solution of the potassium-salt previously made alkaline is precipitated by *baryta-water* in the cold; but in this case, the other elements of the mustard-oil remain in the solution in the form of a compound precipitable by lead-salts, and easily separable into mustard-oil and glucose.

Potash-ley of specific gravity 1.28, mixed with dry myronate of potassium, becomes spontaneously heated to the boiling point, giving off the odour of mustard-oil, cyanide of allyl, and ammonium.

Myronate of potassium, treated with zinc and hydrochloric acid, continually gives off sulphuric acid, which is likewise evolved, though more slowly, by boiling with hydrochloric acid alone. The solution then contains glucose, an ammonium-salt, and half the sulphur in the form of sulphuric acid.

A solution of myronate of potassium, mixed with neutral acetate of lead, yields a yellowish-white precipitate, easily soluble in acetic acid, and apparently containing all the elements of myronic acid. *Mercurous nitrate* forms a yellowish-white precipitate, which is decomposed by heat, with formation of mustard-oil.

When a moderately concentrated aqueous solution of myronate of potassium is mixed with *nitrate of silver*, nitric acid is set free, and a white curdy precipitate is formed, containing, when dried over oil of vitriol, the elements of sulphocyanate of allyl and sulphate of silver ($C^4H^3Ag^2NS^2O^4 = C^4H^3NS.Ag^2SO^4$). Its formation is represented by the equation,

This silver-compound, heated either alone or with water, is resolved into sulphocyanate of allyl, sulphate of silver and sulphide of silver; it is also decomposed, with evolution of mustard-oil, by *chloride* or *sulphide of barium*, or by *zinc*. When it is treated with *hydrochloric acid*, the liquid filtered from the chloride of silver contains half the sulphur in the form of sulphuric acid, but no sulphydric acid or sulphocyanate of allyl is produced. The silver-compound, suspended in a large quantity of water, is decomposed by *sulphydric acid*, with formation of a precipitate of sulphur and sulphide of silver; and the strongly acid filtrate, which contains half the original quantity of sulphur in the form of sulphuric acid, yields by repeated distillation an oily layer, consisting of cyanide of allyl, $C^4H^3.CN$:

The cyanide of allyl thus produced differs considerably in its properties from that which Lieke obtained by the action of cyanide of silver on iodide of allyl (ii. 203). It is a colourless neutral oil of agreeably alliaceous odour and burning aromatic taste. Specific gravity = 0.8389 at 12.8°. Vapour-density = 2.32 (calc. 2.31); boiling point 116° (corrected 118.3°). Heated with strong potash-ley in a sealed tube, it is resolved into ammonia and crotonic acid, $C^4H^3O^2$. (Will and Körner.)

MYROSIN. An emulsion-like substance, of the albuminous or protein class, contained in the seeds of black and white mustard, and possessing the property of decomposing the myronate of potassium contained in the former, with production of sulphocyanate of allyl or volatile oil of mustard. It is likewise contained in the seeds of other cruciferous plants, viz. *Raphanus sativus*, *Brassica Napus*, *Br. oleracea* and *Br. campestris*, *Alliaria officinalis*, *Cheiranthus Cheiri*, *Draba verna*, *Cardamine pratensis*, *C. anara* and *Thlaspi arvense*. (Lepage.)

To prepare it, pulverised white mustard is exhausted with cold water; the filtrate evaporated to a syrup at a temperature below 40°; the syrup precipitated by a moderate quantity of alcohol; the precipitate dissolved in water after the alcohol has been poured off; and the solution evaporated to dryness at a temperature below 40°.

Myrosin, as thus obtained, resembles other protein-compounds. When incinerated, it leaves sulphate of calcium.

In the state of aqueous solution, it is coagulated by heat and also by alcohol, and loses its power of eliminating oil of mustard from myronic acid, but recovers this power after immersion in water for twenty-four to thirty-six hours. It does not eliminate hydrocyanic acid from amygdalin.

The aqueous solution of myrosin is transparent, colourless, and gummy, and froths when agitated. (Bussy, J. Pharm. xxvi. 44; Winckler, Jahrb. pr. Pharm. iii. 93.)

MYROXOCARPIN. (Stenhouse, Ann. Ch. Pharm. lxxviii. 306.)—A crystallisable substance extracted from white Peru balsam (i. 496). On digesting this balsam with alcohol of ordinary strength, a great part dissolves, and the solution gradually deposits large crystals of myroxocarpin mixed with resin; they may be purified by recrystallisation with aid of animal charcoal.

Myroxocarpin crystallises in large thin, colourless, shining prisms, often an inch long. According to a determination by Miller, they belong to the trimetric system, the ratio of the principal axes, macrodiagonal and brachydiagonal, for the primary octahedron P , being as 1 : 0.9363 : 0.7653. Observed combination $\infty P : \infty P' : \infty P'' : 2P \infty : P \infty : 2P \infty$. Angle $\infty P : \infty P' = 102^\circ 12'$; $P \infty : \infty P' = 127^\circ 4'$; $2P \infty : \infty P' = 110^\circ 41'$; $P \infty : \infty P' = 133^\circ 7'$; $2P \infty : \infty P' = 115^\circ 5'$. The crystals are hard and brittle, insoluble in water, very soluble in hot alcohol and ether, tasteless, and neutral to test-papers. They give by analysis 77.18 per cent. carbon, and 9.5 hydrogen, which may be represented by the formula $C^{14}H^{12}O^6$, or $C^{14}H^{12}O^6$.

Myroxocarpin melts at 115° to a transparent glass, which does not crystallise on cooling, but if redissolved in boiling alcohol, is again deposited in the crystalline form. Heated considerably above its melting point, it yields a sublimate, together with much acetic acid, and an uncrystallisable resin.

It does not unite with *acids*, or with *alkalis*, and is not attacked by boiling *potash-ley*.

Hot nitric acid slowly converts it into oxalic acid and an uncrystallisable resin. *Chlorine*, with aid of heat, likewise converts it into an amorphous resin.

MYROXYLIC ACID. The name given by Plantamour to the product of the decomposition of cinnaein (i. 981) by alcoholic potash; probably impure benzoic acid.

MYROXYLON PEREIRAE. The tree which yields Peru balsam. From the bark of this tree there exudes a gum-resin, which, according to Attfield (Pharm. J. Trans. [2] v. 248), contains 77.4 per cent. resin, 17.1 gum (like gum-arabic), 1.5 woody fibre, and 4 water, together with volatile oil. It is uncrystallisable, and its alcoholic solution reddens litmus slightly. This gum-resin is therefore altogether of different nature from the balsam obtained from the fruit of the same tree (i. 496).

MYRRH. A gum-resin which exudes from *Balsamodendron Myrrha*, a terebinthaceous shrub growing in Arabia and Abyssinia. It occurs in large heavy tears of various size, reddish colour, and irregular shape, having an appearance of efflorescence on the surface, semi-transparent, fragile, shining with a greasy lustre on the fractured surface. It has a rough bitter taste, and a strong, very peculiar aromatic odour.

The following are analyses of myrrh:

Resin	23.0	27.8	44.76
Essential oil	2.5	2.6	2.18
Gum	46.0	54.4	40.82
Mucilage			
Foreign matters (potassium-salts of sulphuric, benzoic, malic, acetic acid), &c.	1.4	(foreign matter and ash)	7.51
Water and impurities	1.6		1.45

An alcoholic solution of myrrh concentrated by distillation, deposits as it cools a soft resin, like turpentine, soluble in ether, slightly soluble in caustic potash, and imparting a violet-red colour to nitric and acetic acid.

Another resin, called myrrhin, remains dissolved in the alcohol, and may be obtained by evaporation. It has the odour of myrrh, melts between 90° and 95°, and is soluble in ether. Heated for some hours to 168°, it swells up and gives off acid vapours (acetic or formic acid?), and leaves a red-brown transparent shining mass, without taste or smell, soluble in alcohol and ether, insoluble in cold and very slightly soluble in boiling potash. This product imparts a violet colour to cold nitric acid, and dissolves in sulphuric acid with red-brown colour. It gave by analysis 74.78 per cent. carbon, 8.06 hydrogen, and 17.16 oxygen. (Ruikholdt.)

The essential oil (myrrhol) obtained by distilling the alcoholic extract of myrrh with water, is thick, yellowish, has a rough taste and pungent odour. It thickens and turns brown in contact with the air, dissolves in alcohol and ether, and is precipitated by water from its alcoholic solution in the form of a yellowish milk, acid to test-paper. It contains, according to Ruikholdt, 79.61 per cent. carbon, 10.43 hydrogen, and 9.96 oxygen.

Gladstone (Chem. Soc. J. xvii. 11) has examined the volatile oil obtained by directly distilling myrrh with water. It was very viscid and of a brownish-green colour; and began to boil at about 266°, giving an oxidised oil, which quickly resinised and retained its greenish colour, and strong smell of myrrh, after repeated rectification. Specific gravity = 1.0189 at 15.5°. Index of refraction at 7.5 for the line A, 1.6196; D, 1.5278; H, 1.5472. Rotatory power = - 136.

MYRRHIN and MYRRHOL. See the last article.

MYRTLE. *Myrtus communis*.—The berries of this plant contain, according to Riegel (Pharm. Centr. 1850, p. 319), chlorophyll, a green soft resin, a volatile oil (occurring also in the leaves), a fixed oil, tannin, sugar, citric acid, malic acid, mucus, humous substances, and small quantities of potash and lime.

Of a specimen of the volatile oil of myrtle, examined by Gladstone (*loc. cit.*), three-fourths distilled over between 160° and 176°, leaving a reddish-brown residue which evolved sulphydric acid. The rectified distillate smelt like oil of bay, and exhibited the composition of a hydrocarbon isomeric with oil of turpentine, C¹⁰H¹⁶. Specific gravity = 0.8611 at 15.5°. Index of refraction at 14°, for the line A, 1.4623; for D, 1.4680; for H, 1.4879. Specific rotatory power = + 21°.

MYSORIN. Anhydrous cupric ortho-carbonate, found in Mysore (see CARBONATES, i. 783).

Hyponitromeconic acid	240	Indican	—
Hyponitrous acid	—	Oxindicanin, Oxindicasin, and Indicasin	247
Hypophosphorous acid* (s. Phosphorus, Oxygen-acids of).		Indicanin	248
Hypoclerite	—	Indifulvin	—
Hypostilbite (s. Stilbite).		Indifuscin and Indifuscone	249
Hyposulphamylic acid	—	Indiglein	—
Hyposulpharsenious acid	—	Indigo-blue	250
Hyposulphethylic acid	—	Preparation of Commercial Indigo	
Hyposulphindigotic or Hyposulphoceric acid (s. Indigo-sulphuric acids, iii. 258).		Purification	251
Hyposulphoglutic acid (s. Sulphoglutic acid).		a. Cold Vats:	
Hyposulphomethylic acid	—	1. Copperas or Common Blue vat	—
Hyposulphonaphthalic and Hyposulphonaphthentic acids (s. Sulphonaphthalic acids).		2. Orpiment-vat	252
Hyposulphophosphoric and Hyposulphophorous acids (s. Phosphorus, Sulphides of).		3. Tin-vat	—
Hyposulphuric and Hyposulphurous acids (s. Sulphur, Oxygen-acids of).		b. Warm Vats:	
Hypovanadic acid (s. Vanadium).		1. Wood-vat or Pastel-vat	—
Hypoxanthine	—	2. Potash or Indian-vat	—
Hyssopine	—	3. Urine-vat	—
Hyssop, Oil of	—	Purification by Sublimation	253
Hystatite	241	Preparation of Indigo-blue from Indican	—
I.		Properties	—
Iaspachates	241	Decompositions	—
Iberite	—	Testing and Valuation	255
Ice-spar	—	Indigo-brown	257
Iceland-spar	—	Indigo-gluten	—
Ichthidin	—	Indigo-green	—
Ichthin	—	Indigo-purple	—
Ichthulin	—	Indigo-red	—
Ichthyocoli (s. Gelatin, ii. 826).		Indigo-sulphuric acids	258
Ichthyophthalmite (s. Apophyllite i. 351).		Hyposulphindigotic, or Hypo-sulphoceric acid	—
Icica-resin	—	Sulphindigotic acid and Sulphindigotates	259
Idiotype	242	Sulphophenic acid	261
Idocrase (s. Vesuvian).		Decomposition-products of the Indigo-sulphuric acids:—Sulphoflavic, Sulphofulvic, Sulphorufic, Sulphopurpuric, and Sulphoviridic acids	262
Idrialin	—	Indigotic acid	263
Idrialite	—	Indigoten (s. Indigo-blue).	
Idryl	—	Indigo-white	—
Igasuric acid	—	Indigo-yellow	264
Igasurine	243	Indihumin	—
Iglesiasite	—	Indin	—
Iglite or Igloite	244	Dibromindin	265
Ildofonsite	—	Dichlorindin	—
Ilicic acid	—	Tetrachlorindin	266
Ilicin	—	Ilydrindin	—
Ilixanthin	—	Nitrindin	—
Ilmenite	245	Indin-sulphuric acid	267
Ilmenium	—	Hydrindin-sulphuric acid	—
Iivate (s. Lioevrite, iii. 689).		Leucindin-sulphuric acid	268
Imabensile	—	Indiretin	—
Imasetic acid (s. Isamic acid, iii. 408).		Indirubin	—
Imasatin	—	Indium	—
Imatra stones	—	Induction, Electrical (s. Electricity, ii. 884, 451).	
Imecetin	246	Induction, Magnetic (s. Magnetism, iii. 781).	
Imides	—	Induction, Photochemical (s. Light, Chemical Action of, iii. 680).	
Imperatoria	—	Infusoria	269
		Infusorial earth	—
		Ink	270

	PAGE		PAGE
Ink :		Iodine, Oxides and Oxygen-acids of :	
Black Inks	270	Periodic acid and anhydride	807
Red ink	271	Periodates	808
Blue, Yellow, and Green Inks	272	Iodine, Selenide, Sulphide, and Telluride of (s. Selenium, Sulphur, and Tellurium, Iodides of).	
Sympathetic Inks	—	Iodite, Iodopyrite, Iodic Silver	810
Marking Inks	—	Iodobenzoic acid	—
Printing Ink	—	Iodobrucine	—
Lithographic Ink	273	Iodo-caoutchin (s. Caoutchin, i. 737).	
Inocarpin	274	Iodo-chloro-nitroharmin (s. Harmin, iii. 11).	
Inosic acid	—	Iodocinchonine (s. Cinchonine, i. 979).	
Inosite	276	Iodocinnamic acid	—
Nitro-inosite	—	Iodocodaine	811
Insolonic acid (s. Terephthalic acid).	—	Iodoform	—
Intestinal Concretions	277	Iodolite	812
Intestinal Juice	—	Iodomecone	—
Inulin	—	Iodomeconin (s. Meconin, iii. 861).	
Iodacetic acid	279	Iodomelaniline (s. Melaniline, under Phenylamines).	
Di-iodacetic acid	—	Iodomercurates	—
Iodacetyl	280	Iodomethylamine (s. Methylamines, iii. 997).	
Iodal	—	Iodomethyl-selenious acid (s. Selenious ethers).	
Iodamides and Iodammoniums :		Iodomorphine (s. Morphine, iii. 861).	
1. Iodamides	—	Iodonitricine (s. Nicotine).	
2. Iodammonium	282	Iodonitroharmin (s. Harmin, iii. 11).	
3. Iodide of Iodammonium	—	Iodonitrophenic acid (s. Phenic acid, Derivatives of).	
Iodaniline (s. Phenylamines).		Iodopapaverine (s. Papaverine).	
Iodanistic acid	283	Iodophenylamine (s. Phenylamines).	
Iodarsenious acid (s. Arsenic, Oxy-iodide of, i. 386).		Iodophenylcitraconimide (s. Citraconic acid, Amides of, i. 993).	
Iodates (s. Iodine, Oxygen-acids of, iii. 800).		Iodopianyl (syn. with Iodomeconine).	—
Iodaurates (s. Gold, Iodides of, ii. 929).		Iodoplatinates	—
Iodethylamine (s. Ethylamine, ii. 538).		Iodopropylene (s. Allyl, Iodides of, i. 142).	
Iodethylene (s. Ethylene, Iodated, ii. 579).		Iodopyrite (s. Iodite).	
Iodhydric acid (s. Iodide of Hydrogen, iii. 284).		Iodopyromeconic acid (s. Pyromeconic acid).	
Iodhydrins	—	Iodoquinine (s. Quinine).	
Iodide of Acetyl	284	Iodosalicyclic acid (s. Salicylic acid).	
Iodide of Aluminium	—	Iodostrychnine (s. Strychnine).	
Iodide of Ammonia (s. Iodammonium, iii. 282).		Iodo-substitution-compounds	818
Iodide of Boron (s. Boron, i. 627).	—	Iodosulphide of Antimony (s. Antimony, i. 338).	
Iodide of Hydrogen	—	Iodotellurates (s. Tellurium, Iodide of).	
Iodide of Nitrogen (s. Iodamides, iii. 280).		Iodotoluylic acid (s. Toluylic acid).	
Iodides, Metallic	286	Iolite (s. Dichroite, ii. 320).	
Iodides, Organic	288	Ionaphthin	—
Iodides of Nitrogen (s. Iodamides, iii. 280).		Ipecacuanha	—
Iodides of Phosphorus, Selenium, Sulphur, and Tellurium (s. the several elements).		Ipecuanic acid	814
Iodine	289	Ipomacic acid	—
Sources	—	Iridium	—
Preparation :		Extraction	—
1. From Varec or Kelp	290	Properties	817
2. From the mother-liquor of the Caliche of Peru	291	Iridium, Alloys of	—
3. From Mineral waters	292	Iridium, Carbide of	818
Properties	293	Iridium, Chlorides of	—

	PAGE		PAGE
Lead:		Lead, Alloys of	
Metallurgical Treatment of Lead ores	481	1. With Antimony: <i>Type-metal</i>	—
I. Reduction of Lead ores	—	2. With Arsenic	—
1. Reduction of Sulphur ores in Reverberatory Furnaces	482	3. With Bismuth; 4. With Bismuth and Antimony; 5. With Chromium; 6. With Copper	533
a. Method by double decomposition	—	7. With Manganese; 8. With Mercury; 9. With Mercury and Antimony; 10. With Potassium and Sodium	534
English Process	—	11. With Tin; <i>Pewter, Solder, &c.</i>	—
Carinthia Process	485	12. With Tin and Bismuth: <i>Fusible alloys</i>	536
French Process	486	13. With Tin, Mercury, and Bismuth	—
Analysis of Lead-slugs from Reverberatory Furnaces	487	14. With Tin and Copper: <i>Bronze, Bell-metal, &c.</i>	—
Action of the Gangue	—	15. With Zinc	537
b. Process by Affinity	488	Lead, Antimonide of (p. 532).	
The reduction of Oxygen ores of Lead	489	Lead, Arsenide of (p. 532).	
Spanish Air Furnace or <i>Horno de Gran Tiro</i>	—	Lead, Bromide of	538
2. The reduction of Lead-ores in Blast Furnaces	491	Acetobromide	—
a. The Cupola or Blast Furnace	—	Lead, Bromocarbonate.	—
Silesian Furnace	—	Lead, Bromophosphate and Bromophosphate of	—
Hartz Furnace	—	Lead, Chloride of	—
Analyses of Matts	492	Acetochloride	539
Analyses of Lead-slugs from Blast Furnaces	493	Lead, Chlorocarbonate of	—
Spanish Economic Furnace	495	Lead, Chloriodide of	—
b. The Ore Hearth	497	Lead, Chlorofluoride of	—
The Backwoods Hearth	—	Lead, Chlorophosphate of	—
The American Hearth	—	Lead, Chlorophosphite of	—
The Scotch Hearth	—	Lead, Detection and Estimation of:	
Chemical reactions in the Blast Furnace	501	I. Reactions in the Dry Way	540
II. The Refining of the Lead	504	II. Reactions in Solution	—
1. Desilverisation: Pattinson's Process	—	III. Quantitative Estimation:	
Stagg's Apparatus—Worsley's Apparatus	507	1. Gravimetric methods	—
Parkes' Process	—	2. Volumetric methods	541
Separation of Copper in crystallisation	508	IV. Separation of Lead from other Metals	—
2. Cupellation or Refining of rich Lead	—	V. Valuation of Lead ores:	
The English system	—	a. By the Wet Way	542
Chambers's Steam Blast	510	b. By the Dry Way	—
Johnson's Process	511	Estimation of the Silver	544
The German System	512	VI. Atomic Weight of Lead	546
Separation of Lead from Bismuth	513	Lead, Fluoride of	547
Manufacture of Litharge	514	Lead, Hydro-aluminous (s. Plumbosulphate)	—
3. Reduction of the Pot-dross and Litharge	515	Lead, Iodide of	—
III. Softening of Hard Lead	516	Aceto-iodide	—
Calcination of the Lead	—	Iodo-chloride	—
Pontifex and Glassford's Process	518	Double salts with the Iodides of Potassium and Sodium	—
Reduction of the Dross	519	Lead Ores	—
Separation of the Antimony	—	Lead, Oxides of	549
Cost of treating Spanish Hard Lead	520	Suboxide	—
IV. Smelting of the Slags and other products:		Protoxide	—
1. The English Slag Hearth	—	Red oxide	551
2. The Clausthal Blast Furnace	521	Sesquioxide	553
V. Condensation of the Lead Fume	523	Dioxide or Peroxide	554
Stokoe's Condenser	—	Compounds with acids: <i>Peroxy-plumbic salts</i>	—
Stagg's Condenser	524	Plumbates	555
Analyses of Lead-Fumes	526	Lead, Oxybromide of	—
		Lead, Oxychlorides of	—
		Lead, Oxycyanide of (s. Cyanides, ii. 253).	—
		Lead, Oxyfluoride of (iii. 547).	—

Nitromethide	927	ii. Dyad Metals	958
Mercuric Oxymethide	928	iii. Triad Metals	964
Meroxene	—	iv. Tetrad Metals	965
Meaconic acid	—	v. Pentad Metals	967
Meaconic ether	—	vi. Hexad Metals	968
Meite	—	vii. Heptad Metals	969
Meitene	—	viii. Iron Metals	—
Meitic Alcohol	—	ix. Platinum Metals	974
Meitic Aldehyde	—	Numerical Relations between the	—
Meitic Chloral	—	Atomic Weights of the Metals	975
Meitic Ether	—	Metalumina	976
Meitin-spar	—	Metalysis	—
Meityl-compounds	929	Metamargarcic acid	—
Meitylene or Mesityl	980	Metamerism (s. Isomerism, iii. 415).	—
Tribromomesitylene	—	Metameconic acid (s. Conenic acid, i.	—
Trichloromesitylene	—	1103).	—
Nitromesitylene	—	Metamorphine	—
Dinitromesitylene	—	Metamorphism	—
Nitromesidine	—	Metamyleno	—
Trinitromesitylene	981	Metanaphthalene (s. Naphthalene).	—
Meitylene-sulphuric acid	—	Metantimonic acid (s. Antimony, i. 824).	—
Mele	—	Meta-octylene (s. Octylene).	—
Meleite (s. Scolecite).	—	Meta-oleic acid	—

	PAGE		PAGE
Metapectic acid (s. Pectic acid).		Methylamines and Methylammoniums:	
Metapectin (s. Pectin).		Tetramethylammonium	10
Metaphlorone (s. Phlorone).		Methyl-triethyl-ammonium	10
Metaphosphoric acid (s. Phosphorus, Oxygen-acids of).		Dimethyl-diethyl-ammonium	
Metasilicates	977	Trimethyl-ethyl-ammonium	
Metastannic acid (s. Stannic acid, under Tin).		Trimethyl-bromethyl-ammonium	10
Metastyrol (s. Cinnamene, i. 982).		Trimethyl-vinyl-ammonium	
Metatartaric acid (s. Tartaric acid).		Trimethyl-amyl-ammonium	
Metatercibenthene (s. Turpentine).		Methyl-ethyl-amylamine	
Metatungstic acid (s. Tungstic acid).		Methyl-diethyl-amyl ammonium	
Metaxite	—	Methyl-amyl-aniline (s. Phenylamines).	
Meteorite	—	Methyl-amylic Ether (s. Amyl, i. 205).	
Meteoritic Dust, Iron, Mud, Stones (s. Meteorites).		Methyl-aniline (s. Phenylamines).	
Meteorites	—	Methyl-arsines (i. 400).	
1. Meteoric Iron	—	Methylate of Amyl (i. 208).	
Analyses of Meteoric Iron	979	Methylate of Ethyl (ii. 542).	
2. Meteoric Stones	980	Methylate of Ethylene	10
a. Containing Meteoric Iron	—	Methylate of Potassium and Methylate of Sodium	
b. Without Meteoric Iron	981	Methyl-benzolic or -Benzylenic Ether (s. Benzylenic Ethers, i. 577).	
General conclusions respecting the constitution of Meteorites	982	Methyl-bromosalicylic acid (s. Salicylic Ethers).	
Meteoric Mud	—	Methyl-brucine	
Meteoric Dust	—	Methyl-butyral	
Literature of Meteorites	—	Methyl-camphoric acid (s. Camphoric acid, i. 732).	
Methal (s. Myristic Alcohol).		Methyl-camphrene	10
Methide, Aluminic	983	Methyl-caprinol	
Aluminic Ethide	—	Methyl-caproyl (s. Methyl-hexyl).	
Methide, Boric (s. Methyl, Boride of, iii. 985).		Methyl-carbamic acid (s. Carbamic acid, i. 751; also Methylamine, iii. 997).	
Methide, Mercuric (iii. 927).		Methyl-carbamides	
Methides, Plumbic (iii. 508).		Methyl-carbonates (s. Carbonic Ethers, i. 801).	
Methides, Stannic (s. Tin-radicles, Organic).		Methyl-chloracetol	
Methionie acid	—	Methyl-citric acids (s. Citric Ethers, i. 1001).	
Methoxacetic acid	—	Methyl-chlorosalicylic acid (s. Salicylic Ethers).	
Methplumbethyl (s. Lead-radicles, Organic, iii. 561).		Methyl conine (s. Conine, ii. 6).	
Methstannethyl (s. Tin-radicles, Organic).		Methyl-cyanamide	
Methulmene and Methulmic acid	—	Methyl-cyananiline (s. Phenylamines).	
Methyl	984	Methyl-disulphophosphoric acid (s. Phosphoric Ethers).	
Methyl, Antimonides of (i. 344).		Methyl-dithionic acid	10
Methyl, Arsenides of (i. 400).		Ethyl-trithionic acid	
Methyl, Boride of	985	Methylene	
Ammonia-boric Methide	986	Methylene, Acetate of	10
Compounds of Boric Methide with Fixed Alkalis	—	Methylene, Bromide of	
Methyl, Bromide of	987	Methylene, Chloride of	
Methyl, Chloride of	—	Methylene, Iodide of	
Monochlorinated Chloride of Methyl	988	Methylene, Oxide of: <i>Diozymethylene</i>	
Methyl, Hydrate of: <i>Methylie Alcohol; Wood-spirit</i>	—	Methylene, Sulphides of	10
Methyl, Hydride of (s. Marsh-gas, iii. 854).		Methylene, Sulphocarbonate of	
Methyl, Iodide of	990	Methylene-phosphoniums (s. Phosphorus-radicles, Organic).	
Methyl, Oxide of	—	Methylene-sulphurous acid (s. Sulphurous Ethers).	
Methyl, Plumbides of (iii. 563).		Methylenitan	10
Methyl, Selenide of	—	Methylene-stannamyl, and Methylene-stannethyl (s. Tin-radicles, Organic).	
Methyl, Sulphides of:		Methyl-ethyl-amylamine (iii. 1000).	
Protosulphide	991	Methyl-ethyl-amyl-phenyl-ammonium (s. Phenylamines).	
Disulphide	—	Methyl-ethyl-aniline (s. Phenylamines).	
Trisulphide	992	Methyl-ethylate of Ethylene	
Methyl, Sulphydrate of	—	Methyl-ethyl-carbamide (s. Carbamides, i. 754).	
Methyl, Telluride of: <i>Telluro-methyl</i>	—	Methyl-ethyl-coninium (s. Conine, ii. 6).	
Methylacetal (s. Methylate of Ethylene).		Methyl-ethylic Ether (s. Ethyl-methyl-lic Ether, ii. 542).	
Methylacetone (s. Acetone, i. 81).		Methyl-ethyl-phenylamine (s. Phenylamines).	
Methylal	904		
Methylamines and Methylammoniums	—		
Methylamine	996		
Methylamine-salts	997		
Dimethyldomethylamine	997		
Dimethylamine	998		
Trimethylamine	—		

	PAGE		PAGE
ethyl-ethyl-urea (s. Methyl-ethyl-carbamide).		Microbromite	1014
ethyl-heptylic Ether (s. Heptyl-methyl Ether).		Microclin	—
ethyl-hexyl, or Methyl-caproyl	1008	Microcosmic salt	—
ethylia (s. Methylamine).		Microloite	—
ethylidene-compounds (s. iii. 1005).		Middletonite	—
ethyl-irisine	—	Miemite : (s. Dolomite).	—
ethyl-lactic acid (s. Lactic Ethers, iii. 792).		Miesite (s. Pyromorphite).	—
ethyl-lutidine (s. Lutidine, iii. 738).		Milk	—
ethyl-malic acid (s. Malic Ethers, iii. 799).		Analysis of Milk	1015
ethyl-morphine (s. Morphine, iii. 8056).		Composition of the Milk of different Animals	1016
ethyl-nicotine (s. Nicotine).		Percentage of Fat in different kinds of Milk	1017
ethyl-nitrophenidine (s. Nitranisidine).		Percentage of Sugar	1018
ethyl-nitrosalicylic acid (s. Salicylic Ethers).		Percentage of Ash	1019
ethyl-onanthy	1009	Tests for Milk Adulterations	1021
ethyl-onanthylic Ether (s. Heptyl-methyl Ether, iii. 149).		Milk-quartz	1022
ethyl-oxalic acid (s. Oxalic Ethers).		Milk-sugar	—
ethyl-oxamic acid (s. Oxamic Ethers).		Products of its Transformation :	—
ethyl-parabanic acid (s. Cholestrophane).		1. Lactose or Galactose	1023
ethyl-paratartaric acid (s. Tartaric Ethers).		2. Lactocaramel	1024
ethyl-phenidine (s. Anisidine, i. 304).		3. Gallactic and Pectolatic acids	—
ethyl-phenylamine (s. Phenylamines)		4. Nitrolactin	—
ethyl-plumbines (s. Lead-radicles, Organic, iii. 503).		Millerite	—
ethyl-phosphines and -phosphoniums (s. Phosphorus-radicles, Organic).		Millingtonia	—
ethyl-phosphoric acid (s. Phosphoric Ethers).		Miloschin	—
ethyl-phosphorous acid (s. Phosphorous Ethers).		Minnetosite	—
ethyl-piperidine (s. Piperidine).		Minosa or Acacia Gum	1025
ethyl-piperyl-carbamide (s. Carbamides, i. 757).		Mimotannic acid	—
ethyl-salicylic acid (s. Salicylic Ethers).		Mindereri Spiritus	—
ethyl-selenic and selenious acids (s. Selenic and Selenious Ethers).		Mineral	—
ethyl-stannethyl (s. Tin-radicles, Organic).		Mineral acids	—
ethyl-stibines (s. Antimony-radicles, Organic, i. 344).		Mineral alkali	—
ethyl-strychnine (s. Strychnine).		Mineral Caoutchouc	—
ethyl-sulphuric acid (s. Sulphuric Ethers).		Mineral Chamæleon	—
ethyl-sulphophenic acid or Sulphanisolic acid	—	Mineral Green	—
Methyl-tartaric acid (s. Tartaric Ethers).		Mineral Indigo	—
Methyl-thiosinamine (s. Thiosinamine).		Mineral Kermes	—
Methyluramine	—	Mineral Oil, Pitch, Resin (s. Petroleum).	—
Methyl-ureas (s. Methyl-carbamides, under Carbamides, i. 754).		Mineral Purple	—
Methyl-xanthic acid (s. Xanthic Ethers).		Mineral Tallow (s. Hatchettin, iii. 14).	—
Methysticin	1010	Mineral Turpethum	—
Metoluidine (s. Melobenzylamine; s. Benzylamine, i. 576).		Mineral Waters (s. Water).	—
Mezereum-seeds	—	Mineral Yellow	—
Miargyrite	—	Minette	1026
Miascite	—	Mniium	—
Mica	—	Minjac-Tankawan or Tinkawan	—
I. Potash-micas :	—	Mirabelles (s. Fruit, ii. 714).	—
Muscovite	—	Mirabilite	—
Lepidolite	1012	Misenite	—
II. Magnesia-micas :	—	Mispickel	—
Phlogopite	—	Mistletoe	—
Biotite	1013	Misy	1027
Mica-slate	1-14	Mitis-green	—
Michaelite	—	Mizzonite (s. Meconite, iii. 865).	—
		Mocha-stone	—
		Modumite	—
		Mohsine	—
		Mohsite	—
		Molecule	—
		Molybdenum	—
		Molybdenum, Alloys of	1028
		Molybdenum, Bromides of	—
		Di-, Tri-, and Tetra-bromide	1029
		Molybdic Oxymide	—
		Molybdenum, Chlorides of :	—
		Dichloride or Molybdous Chloride	—
		Trichloride or Molybdoso-molybdic Chloride	1030
		Tetrachloride or Molybdic Chloride	1031
		Ammonio-molybdic Chloride	—
		Molybdenum, Chlorobromides of	—
		Molybdenum : Detection and Estimation :	—
		1. Blowpipe reactions	—

	PAGE	
Molybdenum: Detection and Estimation:		Mountain Green
2. Reactions in Solution	1031	Mountain Soap (s. Steatite).
3. Quantitative Estimation and Separation	—	Mucamide
4. Atomic Weight	—	Mucic acid
Molybdenum, Fluorides of	—	Mucates
Molybdenum Glance	—	Mucic Ethers
Molybdenum, Iodides of	—	Mucidines
Molybdenum, Nitrates and Amides of	—	Mucilage
Molybdenum, Oxides of	1032	Mucin
Protoxide or Molybdous oxide	—	Mucus
Dioxide or Molybdic oxide	—	Mudarin
Trioxide or Molybdic Anhydride	1033	Mudesic acid
Combinations of the Trioxide:		Mudesous acid
1. With Water.—2. With Acids	1036	Mulhouse Blue
3. With Bases: <i>Molybdates</i>	1037	Müller's Glass
Molybdenum, Oxybromides of	1041	Müllerite (s. Sylvanite).
Molybdenum, Oxychlorides of	—	Mullicite (s. Vivianite).
Molybdenum, Phosphide of	1012	Multiplier (s. Electricity, ii. 443).
Molybdenum, Sulphides of	—	Munjeet
Disulphide or Molybdic sulphide	1043	Munjistin
Trisulphide: <i>Sulphomolybdic acid</i>	—	Muntz's Metal
Sulphomolybdates	—	Murchisonite
Tetrasulphide: <i>Persulphomolybdic acid</i>	1045	Murexan
Persulphomolybdates	—	Murexide (s. Purpurates).
Molybdin	1046	Murexoin
Momordica	—	Muriacito
Momordicin	—	Muriatic acid
Monarda, Oil of	—	Murimontite
Monazite	—	Musa
Monazitoïd	—	Muscle
Monesin	1017	Muscovite
Monheimite	—	Muscular Tissue
Mono-compounds	—	Musena bark
Monophane	—	Musenite
Monotropa	—	Musk
Monradite	—	Mussel-shells (s. Shells).
Mourolite	—	Mussite
Montanine	—	Mussonite (s. Parisite).
Monticellite	—	Mustard
Montmorillonite	—	Mustard, Oils of
Moonstone	—	Myocclone
Mordants (s. Dyeing, ii. 352).	—	Myocoderm
Mordenite	—	Mycomelic acid
Moric acid	—	Mycose or Trehalose
Morindin	1018	Myelin
Morindone	1019	Myrica Tallow
Moringic acid	—	Myricin
Morintannic acid	—	Myricyl, Hydrate of
Moroxite	1050	Myristic acid
Moroxylic acid	—	Myristic Alcohol
Morphetine	—	Myristic Anhydride
Morphine	—	Myristic Ethers:
Morphine-salts	1051	Myristica
Iodomorphine	1056	Myristicin
Methyl- and Ethyl-morphine	—	Myristin (s. Myristic Ethers).
Morphium	—	Myristo-benzoic Anhydride
Morpholites	—	Myristone
Mortar	—	Myristyl, Hydride of
Morvenite	—	Myronic acid
Mosaic Gold	—	Myrosin
Mosandrite	—	Myroxocarpin
Moss Agate	—	Myroxalic acid
Mother-liquor	—	Myroxylon
Mother-of-Pearl	1057	Myrrh
Mountain Cork, or Mountain Leather	—	Myrrhin and Myrrhol
Mountain Blue	—	Myrtle
		Myrsin

END OF THE THIRD VOLUME.
